**Improvement in the Bioavailability of Poorly Water-Soluble Drugs via  
Pulmonary Delivery of Nanoparticles**

**by**

**Wei Yang, B.S.; M.S.Ph.D.**

**Dissertation**

Presented to the Faculty of the Graduate School of

The University of Texas at Austin

in Partial Fulfillment

of the Requirements

for the Degree of

**Doctor of Philosophy**

**The University of Texas at Austin**

**August 2009**

## **Dedication**

To my loving and ever-supportive father and mother,  
Mr. Jingsen Yang and Mrs. Fengqing Wang

## **Acknowledgements**

I would foremost like to extend my deepest gratitude to my supervising advisor, Dr. Robert O. Williams III, for providing me the opportunities over the past four years. His insightful guidance, positive attitude, and endless encouragement throughout my entire study lead me to where I am today. I would also like to thank my co-supervisor, Dr. Keith P. Johnston, for his constructive suggestions, experimental ideas, and meticulous guidance to improve my ability to communicate and write scientific papers. I sincerely appreciated the mentorship I received from Dr. James W. McGinity. His extensive and solid knowledge base, his life lessons, his enthusiasm for being a pharmaceutical scientist, and his care of students influence me immensely and will be beneficial to my career and development throughout my life. In addition, I would like to thank Dr. Jason T. McConville for his mentorship during my early years in graduate school, constant encouragement, and willingness to help whenever I have questions. I would also like to express my thankfulness to Dr. Nathan P. Wiederhold for his invaluable help in designing and conducting in vivo studies on inhaled itraconazole, insight into analysis of itraconazole delivery and pharmacokinetics, and guidance to improve my communication ability.

I am very thankful to the College of Pharmacy Staff for making my busy life easier: Ms. Yolanda Abasta, Ms. Mickie Sheppard, Ms. Claudia McClelland, Ms. Joyce McClendon, Ms. Janet Larsen, Mr. Jay Hamman, and Mr. Jim Baker.

I would also like to thank all of the past and present post doctoral fellows, graduate students for their friendship, assistance, and guidance. Specifically, I thank Dr. Jiahui Hu, Dr. Jason McConville, Ms. Jasmine Tam, Dr. Keat Theng Chow, Mr. Bo Long, Dr. Dave Miller, Dr. Jim DiNunzio, Dr. Kirk Overhoff, Dr. Troy Purvis, Dr. Michal Mateucci, Dr. Josh Engstrom, Dr. Shawn Kucera, Dr. Justin Tolman, Mr. Alan Watts, Mr. Kevin O'Donnell, Ms. Piyanuch Wonganan, Ms. Yoen Ju Son, Ms. Sandra Schilling, Ms. Nicole Nelson, Ms. Stephanie Bosselmann, Dr. Caroline Dietzsch, Dr. Dorothea Sauer, Ms. Loni Coots, and many others.

Finally, and most importantly, I express my deepest love and appreciation to my parents, Mr. Jingsen Yang and Mrs. Fengqing Wang for their unconditional love and support throughout every stage of my life. I would also like to thank my brother and all other family members for their love, care and encouragement. Lastly, I would like to extend my gratitude to my best friend Ms. Yubin Wu, my roommates Dr. Xuan Huang and Ms. Qian Wang for their friendship, care and support, which helped me went through hard times when I would need a helping hand most and without my family around.

# **Improvement of Bioavailability of Poorly Water-Soluble Drug via Pulmonary Delivery of Nanoparticles**

Publication No. \_\_\_\_\_

Wei Yang, Ph.D.

The University of Texas at Austin, 2009

Supervisors: Robert O. Williams III and Keith P. Johnston

High throughput screening techniques that are routinely used in modern drug discovery processes result in a higher prevalence of poorly water-soluble drugs. Such drugs often have poor bioavailability issues due to their poor dissolution and/or permeability to achieve sufficient and consistent systemic exposure, resulting in sub-optimal therapeutic efficacies, particularly via oral administration. Alternative formulations and delivery routes are demanded to improve their bioavailability. Nanoparticulate formulations of poorly water-soluble drugs offer improved dissolution profiles. The physiology of the lung makes it an ideal target for non-invasive local and systemic drug delivery for poorly water-soluble drugs.

In Chapter 2, a particle engineering process ultra-rapid freezing (URF) was utilized to produce nanostructured aggregates of itraconazole (ITZ), a BCS class II drug,

for pulmonary delivery with approved biocompatible excipients. The obtained formulation, ITZ:mannitol:lecithin (1:0.5:0.2, w/w), *i.e.* URF-ITZ, was a solid solution with high surface area and ability to achieve high magnitude of supersaturation. An aqueous colloidal dispersion of URF-ITZ was suitable for nebulization, which demonstrated optimal aerodynamic properties for deep lung delivery and high lung and systemic ITZ levels when inhaled by mice.

The significantly improved systemic bioavailability of inhaled URF-ITZ was mainly ascribed to the amorphous morphology that raised the drug solubility. The effect of supersaturation of amorphous URF-ITZ relative to nanocrystalline ITZ on bioavailability following inhalation was evaluated in Chapter 3. The nanoparticulate amorphous ITZ composition resulted in a significantly higher systemic bioavailability than for the nanocrystalline ITZ composition, as a result of the higher supersaturation that increased the permeation.

In Chapter 4, pharmacokinetics of inhaled nebulized aerosols of solubilized ITZ in solution versus nanoparticulate URF-ITZ colloidal dispersion were investigated, under the hypothesis that solubilized ITZ can be absorbed faster through mucosal membrane than the nanoparticulate ITZ. Despite similar ITZ lung deposition, the inhaled solubilized ITZ demonstrated significantly faster systemic absorption across lung epithelium relative to nanoparticulate ITZ in mice, due in part to the elimination of the phase-to-phase transition of nanoparticulate ITZ.

## Table of Contents

List of Tables .....	xiv
List of Figures .....	xv
Chapter 1: Inhaled Nanoparticles – A Current Review .....	1
1.1 Abstract .....	1
1.2 Overview of Nanomaterials .....	1
1.3 Characteristics of nanomaterials .....	2
1.4 The lungs as a delivery target for nanomaterials .....	4
1.5 Deposition of nanomaterials in the respiratory tract.....	5
1.6 The fate of inhaled nanomaterials in the lung.....	7
1.7 Systemic translocation of inhaled nanomaterials.....	11
1.8 Factors influencing the fate of nanomaterials.....	14
1.9 Potential applications of nanomaterials in drug delivery.....	16
1.10 Delivery devices.....	18
1.11 Pulmonary delivery of therapeutic nanomaterials .....	20
1.12 Conclusions.....	23
1.13 References.....	24
1.14 Dissertation objectives and outline .....	33
Chapter 2: High Bioavailability from Nebulized Itraconazole Nanoparticle Dispersions with Biocompatible Stabilizers .....	40
2.1 Abstract .....	40
2.2 Introduction.....	40
2.3 Materials and Methods.....	44
2.3.1 Materials .....	44
2.3.2 Preparation of nanostructured aggregate powder of ITZ using URF technology.....	44
2.3.3 Preparation of physical mixture .....	45
2.3.4 Powder X-Ray Diffraction (XRD).....	45
2.3.5 Scanning Electron Microscopy (SEM) .....	45
2.3.6 Scanning Transmission Electron Microscopy (STEM) .....	46

2.3.7 Thermal Analysis .....	46
2.3.8 True Density Measurements .....	47
2.3.9 Particle Size Analysis by Laser Diffraction.....	47
2.3.10 Brunauer-Emmett-Teller (BET) Specific Surface Area Analysis .....	48
2.3.11 Dissolution Testing at Supersaturation Conditions .....	48
2.3.12 In Vitro Aerosol Performance.....	49
2.3.13 Stability Study.....	49
2.3.14 <i>In Vivo</i> Pulmonary Dosing of Mice .....	50
2.3.15 Plasma and Lung Analysis.....	50
2.3.16 Pharmacokinetic Analysis.....	51
2.4 Results.....	52
2.4.1 Physicochemical Properties of URF–ITZ Powder.....	52
2.4.2 Energy Dispersive Spectroscopy .....	53
2.4.3 Thermal Analysis.....	53
2.4.4 Particle Size Distribution .....	54
2.4.5 Specific Surface Area and True Density.....	54
2.4.6 Supersaturation Dissolution Study.....	55
2.4.7 In Vitro Aerosol Performance.....	55
2.4.8 Stability Study.....	56
2.4.9 Single Dose, 24-h Pharmacokinetic Study in Mice .....	56
2.5 Discussion .....	57
2.5.1 Characterization of URF-ITZ and Comparison to SFL-ITZ.....	57
2.5.2 Role of the surfactant and mannitol .....	59
2.5.3 Deposition of the nanoparticles containing ITZ .....	61
2.5.4 Absorption of ITZ as a function of the composition and particle morphology .....	62
2.6 Conclusions.....	66
2.7 Acknowledgements.....	67
2.8 References.....	67
Chapter 3: Comparison of the Bioavailability of Amorphous versus Crystalline Itraconazole Nanoparticles via Pulmonary Administration in Rats .....	86

3.1 Abstract.....	86
3.2 Introduction.....	87
3.3 Materials and Methods.....	91
3.3.1 Materials .....	91
3.3.2 Preparation of Crystalline ITZ Nanoparticulates and Amorphous Nanostructured Aggregates of ITZ .....	91
3.3.3 Scanning Electron Microscopy (SEM) .....	92
3.3.4 Powder X-Ray Diffraction (XRD).....	92
3.3.5 Modulated Temperature Differential Scanning Calorimetry .....	93
3.3.6 Particle Size Analysis .....	93
3.3.7 Brunauer-Emmett-Teller (BET) Specific Surface Area Analysis .....	94
3.3.8 Dissolution Testing Under Supersaturated Conditions.....	94
3.3.9 <i>In Vitro</i> Aerosol Performance .....	95
3.3.10 <i>In Vivo</i> Pulmonary Dosing of Rats .....	96
3.3.11 Plasma and Lung Analysis.....	97
3.3.12 Pharmacokinetic and Statistical Analysis .....	98
3.4 Results and Discussion .....	98
3.4.1 Physicochemical Properties of Wet-milled ITZ and URF-ITZ Formulations .....	98
3.4.1.1 Morphology and Particle Size Distribution .....	98
3.4.1.2 Crystalline State Evaluation.....	100
3.4.2 Supersaturation of Wet-milled ITZ and URF-ITZ colloidal dispersions in simulated lung fluid .....	101
3.4.3 <i>In Vitro</i> Aerosol Performance of Wet-milled ITZ and URF-ITZ Aqueous Colloidal Dispersions.....	103
3.4.4 Pharmacokinetics of Inhaled Wet-milled ITZ and URF-ITZ in Rats.....	104
3.4.5 Lung Clearance of the Deposited Nanoparticles Containing ITZ .....	106
3.5 Conclusion .....	108

# **Chapter 1: Inhaled Nanoparticles – A Current Review**

## **1.1 ABSTRACT**

The field of nanotechnology may hold the promise of significant improvements in the health and well being of patients, as well as in manufacturing technologies. The knowledge of this impact of nanomaterials on public health is limited so far. This paper briefly reviews the unique size-controlled properties of nanomaterials, their disposition in the body after inhalation, and the factors influencing the fate of inhaled nanomaterials. The physiology of the lung makes it an ideal target organ for non-invasive local and systemic drug delivery, especially for protein and poorly water-soluble drugs that have low oral bioavailability via oral administration. The potential application of pulmonary drug delivery of nanoparticles to the lungs, specifically in context of published results reported on nanomaterials in environmental epidemiology and toxicology is reviewed in this paper.

## **1.2 OVERVIEW OF NANOMATERIALS**

In the current era of nanoscience, the use of nanotechnologies in commercial applications is increasing in many scientific disciplines, including electronics, sporting goods, tires, stain-resistant clothing, cosmetics, and medicine for diagnosis, imaging and drug delivery.

'Nanoscience' and 'nanotechnologies' have been defined by the Royal Society and Royal Academy of Engineering [1, 2] as follows:

*"Nanoscience is the study of phenomena and manipulation of materials at atomic, molecular and macromolecular scales, where the properties differ significantly from those at a larger scale"; likewise, "Nanotechnologies are the design, characterization, production and application of structures, devices and systems by controlling shape and size at nanometer scale".*

Nanomaterials, the building blocks for nanotechnology, are engineered materials with one or more components with at least one dimension measuring 100 nanometers or less. They include nanoparticles, nanofibers and nanotubes, composite materials and nano-structured surfaces. Nanoparticles, as a subset of nanomaterials, are currently defined as single particles with a diameter less than 100 nm. Agglomerates of nanoparticles can be larger than 100 nm in diameter but may be de-agglomerated with weak mechanical forces or by dispersing in a solvent. Nanofibers and nanotubes have two dimensions measuring less than 100 nm but the axial dimension can be much larger.

### **1.3 CHARACTERISTICS OF NANOMATERIALS**

The main differentiating characteristic of nanomaterials is their size, which falls in the transitional zone between individual atoms or molecules and the corresponding bulk materials [3]. Size reduction can modify the physical and chemical properties of nanomaterials distinctively from their bulk and molecular counterparts. It is known that for a group of airborne particles with fixed mass ( $10 \text{ mg/m}^3$ ) and unit density ( $1 \text{ g/cm}^3$ ), as the particle size decreases to less than 100 nm, the number of particles increases exponentially along with the surface area, as shown in Figure 1.1. This allows a greater proportion of atoms or molecules to be orientated on the surface rather than within the interior of the material, hence allowing adjacent atoms and substances to interact more

readily. The surface-to-volume ratio determines the potential number of reactive groups; the intrinsic properties of materials at the nanosized level are emphasized compared to their larger bulk counterparts. The enhanced activities could be either beneficial (e.g. antioxidation, carrier capacity for drugs, increased uptake and interaction with biological tissues) or disadvantageous (e.g. toxicity, instability, induction of oxidative stress) depending on the intended use [4, 5].

Independent of particle size, the charges carried by the materials in contact with cell membranes and the chemical reactivity of the materials play a dominant role when the particles react with other substances or tissues [6].

Due to the attractive properties of nanomaterials (summarized in Table 1.1.), such as high strength, conductivity, solubility, durability and reactivity, they have been used in a variety of applications, including fillers, opacifiers, catalysts, semiconductors, cosmetics, microelectronics, and drug carriers [4, 7]. However, as production and use of engineered nanomaterials have expanded, the potential impact to the environment and human health must be investigated and confirmed [8].

Particle size and surface area of the nanomaterials are important characteristics from a toxicological viewpoint. Carbon black nanoparticles of similar mass and composition but with different specific surface areas (300 versus 37 m<sup>2</sup>/g) were studied. It was found that the biological effects, such as, inflammation, genotoxicity, and histology were related to surface area and not particle mass. Similar findings have been reported regarding tumorigenic effects of inhaled particles. It was shown that the tumor incidence correlated better with specific surface area than with particle mass [9, 10]. It is

recognized that biologically available surface area is probably the most critical parameter for the effects of the nanomaterials. Additionally, particle surface chemistry, biodegradability, number, shape, and solubility are all found to be significant factors in determining harmful biological effects [3, 11, 12].

Knowledge of the effects of nanomaterials on biological systems is limited due to the relative novelty of this technology, and little has been done to assess the risks of nanomaterials to biological systems. The current paradigm in environmental epidemiology is that adverse health effects of fine and ultrafine particulates, such as those found in air pollution and some workplaces, are driven by the ultrafine particle fraction, indicating that exposure to materials in the nano-size range could cause significant public health problems, such as pulmonary and cardiovascular diseases [13-15].

#### **1.4 THE LUNGS AS A DELIVERY TARGET FOR NANOMATERIALS**

The lungs, skin, and intestinal tract are in direct contact with the environment. These organs are likely to be a first port of entry for nanomaterials into the body. Epidemiological studies showed a positive correlation between increases in atmospheric particulate concentrations and the short term increases in morbidity and mortality [15, 16]. Inhalation is the most significant exposure route for airborne nanoparticles [3, 4]. The lung consists of two functional parts, the airways (trachea, bronchi, and bronchioles) and the alveoli (gas exchange areas). The conducting zone consist of the first 16 generations of airways comprised of the trachea (generation 0), which bifurcates into the two main stem bronchi, and subdivides into progressively smaller-diameter bronchi and bronchioles. The respiratory zone consists of all structures that participate in gas exchange and begins with the respiratory bronchioles [17]. The human lungs contain

about 2300 km of airways and 500 million alveoli [18]. The surface area of the human lungs is estimated to be approximately 75-140 m<sup>2</sup> in adults [19-21]. The pseudostratified epithelia that constitute the barrier to absorption into the bloodstream are markedly different in airways and alveoli of the lungs. The airways are composed of a gradually thinning columnar epithelium, with the bronchial epithelium of 3-5 mm and bronchiolar epithelium of 0.5-1 mm in thickness [17, 22]. In the tracheo-bronchial region the epithelium is protected by a mucus layer [23]. Any particle deposited in this area is transported away from the lung by mucociliary clearance [24], or diffuse through the thick mucus to reach the epithelium cells. In contrast, the alveoli have a thin, single cell layer. The distance from the air in the alveolar lumen to the capillary blood flow is less than 400 nm. The large surface area of the alveoli and the intimate air-blood contact in this region make the alveoli less well protected against inhaled substances, such as nanoparticles, as compared to the airways [23].

## **1.5 DEPOSITION OF NANOMATERIALS IN THE RESPIRATORY TRACT**

There are three principal mechanisms that lead to pulmonary deposition: inertial impaction, gravitational sedimentation, and Brownian diffusion, as summarized in Table 1.2. The inertial impaction occurs during the passage through the oropharynx and large conducting airways if the particles possess a mass median aerodynamic diameter (MMAD) more than 5 micron. When the MMAD of particles ranges from 1 to 5 microns, they are subject to sedimentation by gravitational force that occurs in smaller airways and respiratory bronchioles. Sedimentation is influenced by breath-holding. Particles with a MMAD of less than or equal to approximately 0.5 micron, they are deposited significantly by diffusion, based on the Brownian motion [23, 25, 26].

The site, extent and efficacy of particle deposition after inhalation is influenced primarily by three factors (aerosol properties and physiology) during breathing: (a) particle/droplet size (diameter), density, surface properties, or shape (i.e. fibers) [27]; (b) anatomy of the upper and lower airways and the alveolar structure; (c) ventilatory parameters with impact on the particle deposition are breath pattern (including breath-holding and presence of expiratory flow limitation), flow rates and tidal volume, determining the airflow velocity and the residence time in the respiratory tract [25, 28, 29].

Next to morphological characteristics and ventilation parameters, the particle size and geometry is most important [25]. The particle size is commonly referred to the aerodynamic diameter, which is a variable depending on the shape, density and size of the object. If aerosols contain different particles, the size distribution is usually characterized by MMAD, which is particularly important to determine whether the particles will be efficiently deposited deep into alveolar region [21, 30]. A successful deposition into deep lung requires the particles be small enough to avoid deposition by inertial impaction on upper airways and can pass through the lower airways, meanwhile be large enough to avoid exhalation [31, 32]. The optimal particle size for achieving delivery deep into alveolar region has been established to be an aerodynamic diameter between 1 and 3 microns [33]. In general, aerosol particles measuring less than 1 micron can be exhaled up to 80% after inspiration without being deposited, because of their low inertia [34, 35]. The deposition of particles in the lung; however, is bi-modal and ultra fine particles (less than 100 nm) appear to settle effectively to the alveolar region with a fractional deposition of around 50%, as calculated with mathematical modeling of monodisperse particles after slow inhalation with a breath hold (see Figure 1.2.) [23, 33,

36]. This has been confirmed by controlled clinical studies evaluating deposition and effects of laboratory-generated ultra fine particles. High deposition efficiencies in the total respiratory tract of healthy subjects were found, and deposition was even greater in subjects with asthma or chronic obstructive pulmonary disease [37, 38].

Nanoparticle deposition in the respiratory tract is determined predominantly by diffusional displacement due to the thermal motion of air molecules interacting with particles in the inhaled and exhaled air streams [39, 40]. Depending on the particle size, shape and ventilation parameters, deposition occurs in all regions of the lung: the airways and the alveoli. With decreasing particle diameter below about 500 nm, the deposition increases in all regions of the lung because of the increasing diffusional mobility [33]. Nanofibers with a small diameter will penetrate deeper into the lungs, while very long fibers (more than 20 microns) are predominantly located in the upper airways [41, 42].

## **1.6 THE FATE OF INHALED NANOMATERIALS IN THE LUNG**

The fate of inhaled nanomaterials depends on regional distribution in the lung, because disposition within the lung is a complex function of the kinetics of absorption and non-absorptive clearance mechanisms [43]. Once nanomaterials are deposited onto the lining of the respiratory tract, they first contact the mucous layer within the airways or the surfactant lining fluid layer within the alveolar region. Airway mucus (about 5 microns in depth) is a complex aqueous secretion of airways, comprising electrolytes, proteins, glycoproteins (e.g. mucins), and cell debris [44]. The components vary much depending on environmental and disease states. The surfactant lining layer (10-20 nm in thickness) that covers the alveolar surface is composed of 90% in weight of phospholipids and 10% in weight of specific proteins [45, 46]. Both airway and alveolar

surface liquids are coated with at least a monolayer of highly surface active lung surfactant, which are primarily water insoluble long chain phospholipids. They form liquid crystals but not micelles in aqueous media [22] to maintain the functions of the lungs: facilitation of gas exchange and prevention of alveoli collapse by reducing the lung air interface surface tension [47, 48].

It was found that regardless of the nature of the nanomaterials surfaces, they will be submersed into the lining fluids after their deposition [40]. Study of interactions between different nanoparticles and lung surfactant film indicated that the smaller the size of nanoparticle, the more can be incorporated into the surfactant film. However, the surface pressure of the surfactant film does not change significantly with the incorporation of nanoparticles, i.e. the size dependent incorporation of nanoparticles does not destabilize the lung surfactant film [49]. D-alpha-tocopheryl polyethylene glycol 1000 succinate (TPGS) coated nanoparticles also do not destabilize the model surfactant film, suggesting potential application of nanoparticles to lungs [50].

Once deposited within the lung lining fluid, there are separate biokinetics for lung absorption and non-absorptive clearances. The kinetics of dissolution of inhaled particulates determines whether the inhaled nanomaterials will dissolve in the epithelial lining fluid for lung absorption or whether such nanomaterials will undergo non-absorptive clearances [51]. Inhaled nanomaterials that are either lipid soluble, or soluble in intracellular or extracellular fluids undergo chemical dissolution in situ. Low molecular weight hydrophobic molecules are thought to be rapidly absorbed (within seconds) by passive diffusion through the lung epithelial membrane [52]. The kinetics of diffusion in the alveoli is much faster than that of the small airways, mainly because lung

absorption mostly occurs from the air-side surface of the alveoli to the pulmonary capillaries. The alveoli has a thin monolayer (0.1- 0.4 micron) composed of extremely broad and thin Type I cells and small compact Type II cells, and a large surface area (more than 100 m<sup>2</sup>). Only a small portion of inhaled nanoparticles is absorbed from the tracheobronchial airways which have a much thicker layer of column-shaped epithelial cells (10–60 microns) and lower surface area (1– 2 m<sup>2</sup>) [29]. This is supported by Fick's law. Low molecular weight hydrophilic molecules can be absorbed by active transport via specific transporters, or by passing through the tight junctions [22]. The kinetics of active absorption should depend upon the lung-regional expression and functionality of receptors or transporters. It was recently reported that the absorption of large molecule immunoglobulins of the IgG class (150 kDa) might occur in the upper airways by receptor-mediated transcytosis of IgG [53, 54]. Solutes and soluble components may be eventually cleared into blood and lymphatic circulation.

Inhaled nanomaterials that are insoluble in mucus and lining fluid, are not able to be rapidly absorbed, and may undergo physical translocation. This is different depending on lung region in which the nanoparticles have been deposited [4]. Immersion of the inhaled, slowly dissolving or insoluble nanomaterials in the fluid lining the lungs may enable them to be closely associated with epithelial cells and cells of the host-defense system for particle-cell interaction [40]. Subsequently, several post defense mechanisms, including the mucociliary escalator transport, phagocytosis by macrophages and endocytosis, are involved in the removal of deposited nanoparticles and to maintain the lung mucosal surfaces [55, 56].

The mucociliary escalator dominates clearance of nanoparticles from the upper airways. Nanoparticles that consist of slowly dissolving or insoluble materials in the airway mucus will be partly moved by action of the ciliated epithelial cells pushing the mucus along with the nanoparticles that deposited on the airway walls to the larynx, where they are swallowed to the gastrointestinal tract or excreted through the mouth [34]. The deposited nanoparticles may also be removed by coughing within 1–2 days [22]. However, Schurch et al. showed that mucus clearance can be overcome by nanoparticles, possibly due to rapid displacement of particles to the airway epithelium via surface energetics [39].

Clearance of the slowly dissolving and insoluble nanoparticles from the alveoli is predominantly by macrophage phagocytosis and endocytosis [57]. The air-side surface of each of the 500 million alveoli in the human lungs is routinely monitored by 12–14 alveolar macrophages in the lung lining fluid [18]. The uptake of deposited particles by alveolar macrophages depends on the particle size and composition of coating material. Particles of 1–3 microns in diameter are far better taken up than those of 6 microns by macrophages, which have cell diameters about 15–22 microns [58]. Particles of less than 0.26 micron can escape from phagocytosis by macrophages [59]. Due to the small size, the chance of nanoparticles undergoing phagocytosis in the alveoli is much lower than micron sized particles. The remaining nanoparticles will interact with the non-phagocytic cells of the epithelium, and the endocytic events are regulated by clathrin-coated pits and caveolae, as well as scavenger receptors (e.g., scavenger receptor SR-A). It has been suggested that caveolae and coated pits preferentially transport small and large particles, respectively, but this needs to be further verified in vivo [60]. Caveolae are indentations of the plasma membrane lined with caveolin-1, and are abundantly expressed on lung

capillaries and type I alveolar cells. Macromolecules or particles of several nanometers in radii may be transported within caveolae from lung to blood [55, 60].

Transport via pores, as suggested for lung-blood substance exchange, is another possible route of disposition of inhaled nanomaterials. Inspiratory expansion and expiratory contraction of lung alveoli may lead to the opening and closing of the caveolae. These openings measure between 40 to 100 nm in size and are thought to be involved in the transport of macromolecules, such as proteins, across the alveolar-capillary barrier [22]. Additionally, a reactive nanomaterial surface will be able to initiate chemical interactions between nanoparticles and membranes by inducing lipid peroxidation at the interface, causing changes in membrane permeability and dynamics [5]. Thus, depending on size and surface reactivity, nanoparticles may be transported across cellular and sub-cellular membranes by different mechanisms. As a result most nanoparticles will be no longer retained as free particles on the epithelium as inhaled and deposited.

### **1.7 SYSTEMIC TRANSLOCATION OF INHALED NANOMATERIALS**

Recently, it was reported that inhaled nanomaterials may also influence organs other than the lungs. Inhaled ultrafine technetium ( $^{99m}\text{Tc}$ ) labeled carbon particles, which are very similar to the ultrafine fraction of actual pollutant particles, diffused into the systemic circulation of hamsters within 5 minutes. Nemmar et al. concluded that phagocytosis by macrophages and/or endocytosis by epithelial and endothelial cells may be responsible for particle-translocation to the blood, along with other mechanisms [61]. There are recent reports that inhaled nanoparticulates have been found in the brain,

probably traveling from the nasal nerves [62]. This suggests that nanoparticles may travel to sites away from the site of deposition in the lungs.

However, no definite conclusion about the systemic translocation of inhaled nanoparticles can be drawn to date, based on the conflicting results of human and animal studies. It was reported that rapid translocation to the liver (more than 50%) of <sup>13</sup>C-labeled nanoparticles with a diameter of 26 nm occurred within 24 hours following inhalation in a rat model [42]. In another rat study, only less than 1% iridium nanoparticles (15–20 nm in diameter) were found in secondary organs of rats, but the nanoparticles were distributed widely throughout the body to such organs as liver, spleen, kidneys, brain and heart [63]. Kato et al. [64] has provided morphological data showing that inhaled polystyrene particles are transported into the pulmonary capillary space, presumably by transcytosis; nevertheless, other research groups did not find any detectable particulates in the body other than the lungs [65, 66].

The variable results from extrapulmonary translocation of experimental nanoparticles may be due to differences in the chemical composition, particle size, surface characteristics, labeling materials and experimental models reported in the different studies. Taken together evidence from the *in vivo* studies for alveolar translocation of inhaled nanomaterials, supports that this pathway exists in humans; however, the extent of extrapulmonary translocation is determined by characteristics of the nanomaterials. Systemic translocation of the inhaled nanomaterials could better explain the epidemiological findings of adverse cardiovascular effects found in communities with air pollution [67].

Inhaled nanoparticles may end up in systemic circulation and the lymphatic system once they reach the pulmonary interstitial sites following transcytosis across alveolar epithelial cells [4]. There is uncertainty regarding the real contribution of the lung's lymphatic pathway to systemic appearance following inhalation of nanoparticles. In the respiratory system, a vast network of lymphatic vessels drains both the airways and the alveolar regions and terminates in the hilar and mediastinal lymph nodes [68]. Lymphatic drainage is responsible for alveolar clearance of deposited drugs and particulates up to a certain particle diameter, *i.e.* 500 nm [69, 70]. In vivo pharmacokinetic studies of radiolabelled solid lipid nanoparticles (mean diameter of 200 nm) revealed significant lymphatic uptake and a high rate of distribution in periaortic, axillar and inguinal lymph nodes after inhalation in rats [71]. For the deposited nanoparticles that are insoluble in the lining fluid of the lungs, they are taken up less efficiently by the macrophages [58]. The phagocytosed nanoparticles may be destroyed once within the lysosomes of phagocytic cells. Therefore it is evident that for the nanoparticles consisting of protein drug, macrophage engulfment usually means eventual digestion of the protein [72]. The nanoparticles sequestered by the macrophages may also be transported to regional lymph nodes and may subsequently migrate to systemic circulation. Particle-loaded macrophages were seen in pulmonary lymphatic vessels and in hilar lymph nodes of animals following instillation of particulates into the airways [68]. It has been shown that transfer of nanoparticles to the lymph nodes of the lung generally increases with increasing molecular weight greater than 10–20 kDa, whereas molecules less than 10 kDa are unlikely to be involved in this pathway [73]. The extent of elimination of inhaled nanoparticles from the different pathways is highly dependant on the nanomaterial characteristics (e.g., particle size, coating, surface charges), the

amount of inhaled nanoparticles, and potential degradation by lysosomal enzymes before transport to the lymphatic circulation.

## **1.8 FACTORS INFLUENCING THE FATE OF NANOMATERIALS**

Clearance of inhaled nanoparticles from the lungs depends mainly on particle size and, by implication, on particle surface characteristics. It was reported following three months exposure of rats to ultrafine (~20 nm) and fine (~200 nm) titanium dioxide (TiO<sub>2</sub>) particles by inhalation, the ultrafine particles were cleared significantly more slowly, and showed more translocation to interstitial sites and to regional lymph nodes as compared to the fine TiO<sub>2</sub> particles [74]. Particles between about 20 and 50 nm in diameter may enter into the central nervous system and cells. In addition, alveolar macrophages on the surface of the lungs appear not be able to recognize particles of less than 70 nm as being “foreign”, thus allowing them to gain access to the pulmonary interstitium, and then capillary blood flow [75].

Particle shape may also interfere with the clearance mechanisms. Nanofibers measuring more than 20 microns in one axis are too long to be phagocytosed (fibers longer than the diameter of the alveolar macrophage) and will be cleared very slowly, staying in the lungs for months and possibly years. They induce a rather general non-specific pulmonary inflammatory response, including release of chemokines, cytokines, reactive oxygen species, and other mediators, which can result in sustained inflammation and eventually fibrotic changes [3, 16].

Surface coating of nanoparticles was found to effect particle uptake. Albumin, lecithin, polysorbate 80, or peptide attachments can enhance nanoparticle uptake into

cells, whereas polyethylene glycol interferes with nanoparticle uptake into the liver [76]. Kato et al. administered intact or lecithin-coated insoluble polystyrene latex beads (240 nm in diameter) intratracheally to rats using an air jet nebulizer. Scanning electron micrographs of the rat lungs showed that both lecithin-coated and uncoated beads were incorporated into alveolar macrophages. Some of the ingested beads in the alveolar macrophages were sequestered within lysosomes. Types I, and II alveolar epithelial cells and monocytes in the capillary lumen selectively incorporated only lecithin-coated beads. These findings suggest that alveolar epithelial cells can incorporate exogenous particles, which are then transferred from the alveoli to intravascular spaces by transcytosis. The interaction between cells and the lecithin-coated particles may involve cellular ligands to recognize the lecithin by virtue of its molecular charge or hydrophilicity. Also, as observed with lecithin, albumin coating of inhaled nanoparticles appeared to facilitate nanoparticle endocytosis [64].

Moreover, surface electrostatic charge is an important factor influencing the deposition of inhaled nanoparticles. Charged nanoparticles have higher deposition efficiencies as compared to neutrally charged nanoparticles. Moderately lipophilic compounds with a positive charge at physiological conditions, such as pentamidine and verapamil, are preferentially bound to lung tissue [77]. Polycationic macromolecules show a strong interaction with cell membranes *in vitro*. Three polycationic paint components exhibited considerable cytotoxicity (LD50 generally below 100 mg/ml for an incubation period of 20–24 hours) in primary cultures of rat and human type II pneumocytes, alveolar macrophages and human erythrocytes. The authors argued that the multiple positive charges play an important role in the toxic mechanism [78, 79]. It was

found that nanoparticles with polar surfaces showed different translocation rates across respiratory epithelium and into circulation in a hamster model [61].

## **1.9 POTENTIAL APPLICATIONS OF NANOMATERIALS IN DRUG DELIVERY**

Learning from environmental toxicology studies, nano-sized air pollutants, especially the spherical solid materials, easily enter the lungs and reach the alveoli, and subsequently are cleared from the lungs by different clearance mechanisms. However, due to their small size, nano-sized particles are not likely to be detected around the lung epithelial barriers. They will translocate into systemic circulation and target other organs. Since the definition for the cut-off size of airborne nanoparticles is the same as that of engineered nanoparticles (100 nm), they should share the same biokinetics upon inhalation into the lungs. Furthermore, the high surface-to-volume ratio of natural airborne and engineered nanomaterials renders them more reactive, even though they are inert as larger particles. Therefore any possible effects of the nanomaterials may be amplified once entering the body via inhalation. On the other hand, the extrapulmonary toxicity induced by inhaled nanosized air pollutants may also provide evidence for systemic delivery of nanosized pharmaceutical agents by inhalation, for the medicines not suitable for oral or parenteral administration to improve bioavailability and patient compliance.

Due to rapid advances in nanotechnology and biotechnology, nanoparticles have been considered as an effective form for delivery, and have been studied extensively to deliver the new generation of protein-, gene-based macromolecular therapeutic agents into the body, since many of the components of living cells are constructed at the nano level, such as ribosomes, membrane transporters, receptors and cell signaling systems

[80]. Nanoparticles fall in the same size range of the biological entities; therefore they can readily interact with molecules on both the cell surface and within the cell [81, 82]. Furthermore, drugs that are deposited within the lungs in nanoparticulate form have a greater chance to escape from the clearance mechanisms by the lung defense systems, compared to micro particulate form [39, 58]. Thus, drug-bearing nanoparticles have the potential to deliver drugs efficiently to the epithelium, while avoiding unwanted mucociliary clearance. In the pharmaceutical area, most nanoparticles described in the literature for drug delivery are between 50 to 500 nm in diameter [83].

Nanoparticles are useful to deliver water insoluble drugs. Despite high potency, the effectiveness of water insoluble drugs can be severely limited because the solubility is too low to reach therapeutic systemic concentrations. However, when their size is reduced to nano level, the increased particle surface-to-volume ratio helps to enhance solubility and dissolution rate in an aqueous environment. Nanoparticulate forms of drug could have an enormous benefit by significantly improving systemic bioavailability (defined as the rate and extent of therapeutically active drugs reaching the systemic circulation) and allowing a more rapid onset of therapeutic action [84].

The route of administration is as important as the drug itself for therapeutic success. Nano-based approaches to drug delivery are focused on crossing a particular physical barrier, such as the gastro-intestinal epithelium for absorption of macromolecules, blood–brain barrier; or on finding alternative and acceptable routes for the delivery of drugs expensive and vulnerable to the gastro-intestinal environment. Pulmonary delivery of drugs at the nano level is a non-invasive promising means to provide not only local lung effects but possibly high systemic bioavailability.

## **1.10 DELIVERY DEVICES**

Aerosols are an effective method to deliver therapeutic agents to the lungs. Nebulizers, metered dose inhalers (MDIs), or dry powder inhalers (DPIs) are commonly used to generate aerosols [85, 86]. Despite the above mentioned advantages of nanoparticles, the use of a drug-bearing nanoparticle itself for delivery to lungs is severely limited because their low inertia causes them to be exhaled after inspiration. Moreover, their small size leads to particle aggregation due to their high surface energy, making handling of nanoparticles very difficult [87]. Therefore, the drug-bearing nanoparticles require carriers with MMADs suitable for efficient pulmonary delivery.

In contrast to the conventional micron sized particulate drug formulations for nebulizers, the drug-bearing nanoparticles in an aqueous colloidal dispersion are more easily incorporated into the “respirable percentage” of aerosolized droplets [88]. Therefore, more nanoparticles can be enveloped into the aerosol droplets and delivered to deep lung. For instance, assuming the particles are spherical, if the volume fraction of particles in the carrier solvent is 0.01, only about 1/100th of 3  $\mu\text{m}$  carrier droplets will contain a 3  $\mu\text{m}$  particle; whereas each carrier droplet would contain about ten 300 nm particles. Thus, nanoparticle colloidal dispersions, relative to microparticle dispersions, have the potential to increase the rate of drug absorption by promoting more uniform drug distribution throughout the alveoli [89, 90].

For pulmonary delivery of drug formulations in solid form, micron sized powder particles containing the drug-bearing nanoparticles were designed for deep lung delivery by using MDIs and DPIs. Sham et al. [91] developed a platform for aerosol delivery of

nanoparticles by preparing carbohydrate (e.g. lactose, mannitol) carrier particles containing nanoparticle clusters using spray drying technique. Carrier particles can be made with an appropriate MMAD to optimize alveolar deposition. Dispersion of the lactose carrier containing either gelatin or polybutylcyanoacrylate nanoparticles by a DPI showed a fine particle fraction (FPF; defined as the percentage of droplets with an aerodynamic diameter less than 4.7  $\mu\text{m}$ ) of about 40% and MMAD of 3 microns. Upon reaching the deep lung and contacting with the aqueous lining fluid of the lung epithelium, the carrier particles dissolved and released the nanoparticles. A novel type of effervescent carrier particle containing nanoparticles, with a MMAD suitable for deep lung delivery, was reported by Ely et al. [92]. Incorporation of effervescent technology into carrier particles adds an active release mechanism for the nanoparticles after pulmonary administration using DPI. Nanoparticles were observed to be distributed throughout the gas bubble that caused by the effervescent reaction when exposed to humidity. Another idea reported for pulmonary delivery of nanoparticles is forming trojan particles, which can be formed by incorporation of nanoparticles into a thin-walled micron sized large porous particles (LPPs) [31]. LPPs, characterized by geometric sizes larger than 5 microns and mass densities around 0.1  $\text{g}/\text{cm}^3$  or less, offer advantage of higher aerosolization efficiency over conventional inhaled therapeutic aerosol particles [93]. In addition, LPPs with geometric diameters of 10–20 microns can penetrate deep into the lungs and avoid macrophage engulfment by virtue of their large size [93, 94]. The trojan particles reportedly have several attractive features: they are comprised solely of nanoparticles; they are readily redispersed as nanoparticles in solution, yet the trojan particles are readily dispersed as aerosols. By using these micron sized carriers to deliver nanoparticles to deep lung, benefits of aerosolization properties of micron particles and the drug release and delivery advantages of nanoparticles can be combined.

### **1.11 PULMONARY DELIVERY OF THERAPEUTIC NANOMATERIALS**

Drug loaded nanoparticles have the potential to be used for pulmonary delivery of therapeutics for treating lung diseases locally and exerting systemic actions. Delivery of therapeutic agents to the site of action for lung diseases may allow for efficient treatment of chronic lung infections, lung cancers, tuberculosis and other respiratory pathologies [95].

In vivo studies have observed an accumulation of nanoparticles in tumor sites after intravascular administration [96], due to the leaky blood vessel structure of tumors. Such properties make nanoparticles a very attractive delivery vehicle for lung cancer treatment. Polysorbate 80 coated nanoparticles which were loaded with doxorubicin (DOX) have been developed to treat lung cancer. The nanoparticles were then incorporated into inhalable carrier particles by a spray-freeze-drying technique [97]. DOX-loaded nanoparticles had a particle size of  $173 \pm 43$  nm after re-dissolving the carrier particles. Cytotoxicity was assessed by incubated cultured monolayer of two lung cancer cell lines (H460 and A549) with DOX-nanoparticle (powder form) at the concentration of  $0.625 \mu\text{g/mL}$  for 24 h. The DOX-loaded nanoparticles showed enhanced cytotoxicity in a concentration dependent manner, compared to free DOX. This indicates that DOX-loaded nanoparticles are more effective than free drug. The enhanced activity of DOX-loaded nanoparticles resulted from the nanoparticles being more readily internalized by an endocytosis mechanism compared to a passive diffusion mechanism of DOX into cells. This study supports the approach of lung cancer treatment using nanoparticles as a drug delivery vector. The carrier particles containing DOX-loaded nanoparticles may be delivered by a dry powder inhaler. Development of inhalable nanoparticles loaded with

bioactive molecules is a new delivery platform which can allow targeting of lung specific diseases in the future.

Solid lipid nanoparticles (SLN) are lipophilic particulates consisting of a spherical solid lipid matrix, and can be used as an efficient and non biotoxic drug carrier for drug delivery [98]. Recently, SLN have been proposed as carriers of either diagnosis or therapeutic reagents upon encapsulation of cytotoxic drugs. Videira et al. [71] prepared lipid nanoparticles using glyceryl behenate by a melt homogenization technique and radiolabelled with  $^{99m}\text{Tc}$  using the lipophilic chelator D,L-hexamethylpropyleneamine oxime (HMPAO). Thus obtained SLNs have a mean diameter of 180-220 nm. Biodistribution studies were carried out following ultrasonic nebulization of an aqueous dispersion of the  $^{99m}\text{Tc}$ -HMPAO-SLN and administration of the aerosols to rats by inhalation using a mask. Dynamic images were obtained up to 4 hours post-inhalation, and showed a significant uptake of the radiolabelled SLN into the lymphatic system after inhalation, and a high rate of distribution in periaortic, axillar and inguinal lymph nodes. The results revealed an important role of the lymphatic pathway in the uptake of inhaled nanoparticulates. This study suggested the possibility of pulmonary delivery of radiolabelled SLN as a lymphoscintigraphic agent and direct delivery of cytotoxic drugs to target lung cancer, which may metastasize through lymphatic drainage.

In vivo pulmonary delivery of 5-fluorouracil (5-FU) in lipid-coated nanoparticles (LNPs) system to a hamster model was recently reported [99]. The 5-FU lipid-coated nanoparticles consisted of a core composed of 20% (w/w) 5- FU, 20% (w/w) FITC-dextran, and 60% (w/w) poly- (glutamic acid) with a shell composed of 33% (w/ w) cetyl alcohol and 67% (w/w) tripalmitin. The cores measure 600 nm in diameter and the shells

measure 200 nm in thickness. The LNPs were suspended at 5 mg/mL in 0.01% Pluronic F68 aqueous solution and atomized into droplets using an ultrasonic driver. The produced droplets were dried and then directed into a nose-only rodent aerosol exposure chamber for inhalation by hamsters at a dose of 30 mg LNPs/kg body weight (1.5 mg 5-FU/kg body weight). The pharmacokinetics of the 5-FU lipid-coated nanoparticle and total 5-FU in the lung, trachea, larynx, esophagus, and serum was studied. It was found that effective local targeting as well as sustained efficacious concentrations of 5-FU in the expected tumor sites were achieved. The results suggest using 5-FU containing lipid-coated nanoparticles for treating squamous cell carcinoma of the lung.

Besides the success in delivering macromolecules via inhalation to systemic circulation, the potential of pulmonary delivery of small molecule weight entities that encounter formidable biopharmaceutical challenges with conventional routes (e.g. oral) of administration was also explored. Itraconazole (ITZ), a poorly water soluble compound, has displayed low and erratic absorption following oral administration. It has been used for treating invasive fungal infections, which quite often gained entry to the body from lung, and may disseminate to the circulation in immune suppressed patients. Two formulations of amorphous nanoparticulate ITZ using polymers and surfactants as excipients were prepared by spray freezing into liquid (SFL) technology. One is designed for pulmonary delivery (ITZ-pulmonary). Eight milliliters of the aqueous colloidal dispersion of the ITZ-pulmonary nanoparticles (containing 200 mg of ITZ equivalent) was aerosolized by a micro pump nebulizer. The aerosols were administered to mice via inhalation exposure for 20 minutes at a dose of 30 mg/kg body weight of ITZ. The other (ITZ-oral) is for oral delivery [100]. The pharmacokinetic profiles of the two formulations were compared with the commercial product Sporanox® oral solution

(itraconazole/Janssen) after repeated dosing. ITZ-pulmonary achieved significantly greater (more than 10-fold) lung tissue concentrations compared to the Sporanox oral solution and ITZ-oral. There were no statistical differences between the two oral formulations. ITZ-pulmonary achieved significantly greater lung levels per unit serum concentration compared to the orally dosed ITZ compositions. High and sustained lung tissue concentrations were achieved via inhalation of an amorphous nanoparticulate ITZ-pulmonary formulation while maintaining serum levels above the minimum lethal concentration of *Aspergillus fumigatus*. This study and other related research [101, 102] showed a paradigm of treating disseminated lung infection by pulmonary delivery of nanosized therapeutics to achieve both high lung local and sufficient systemic drug concentrations to effectively improve survival.

Budesonide, another poorly water soluble drug has been prepared as a nanosuspension by high-pressure homogenization and delivered by nebulization [90]. This budesonide nanosuspension has a mean particle size about 500-600 nm, 99% of the nebulized aerosols were below 3 microns; and the nanosuspension also displayed long-term stability without aggregation or particle growth occurring over the examined period of 1 year. The manufacturing technology is feasible to scale up. These features of the budesonide nanosuspension imply the potential of successful in vivo pulmonary application. However, it is regretted that no in vivo experiments were reported to study the pharmacokinetics and effects of the budesonide nanosuspension.

## **1.12 CONCLUSIONS**

While nanotechnology provides great promises in healthcare, the potential risk imposed by natural and engineered nanomaterials to public health has also been of

concern. This is due to their enhanced activity at the nano-scale. The potential of the lung as a natural entry route for systemic delivery of aerosols of macromolecules that are otherwise vulnerable to enzyme degradation in the gastrointestinal tract, and of water insoluble drugs, has been recognized in the pharmaceutical field. The integration of nanotechnology and pulmonary delivery of drug aerosols represents a new and exciting frontier for pharmaceutical dosage form design to increase bioavailability and patient compliance, as supported by the results of studies using nanoparticles as either diagnostic or therapeutic agents for lung and systemic diseases.

## **1.14 DISSERTATION OBJECTIVES AND OUTLINE**

High throughput screening techniques routinely used in modern drug discovery processes result in a higher prevalence of poorly water-soluble active pharmaceutical ingredient (API). Such APIs often have poor bioavailability issues due to their poor dissolution and/or permeability to achieve sufficient and consistent systemic exposure. Consequently it results in sub-optimal efficacy in patients, particularly via oral administration. Alternative formulations made by novel pharmaceutical technologies for improving the dissolution properties and thereby bioavailability of the poorly water-soluble APIs are becoming increasingly important to modern drug delivery. Alternative delivery routes are also important to enhance drug bioavailability. The overall objective of this dissertation was to formulate, fully characterize nanoparticle formulations of poorly water-soluble drug through in vitro and in vivo tests. Formulations were produced and evaluated based on current needs of clinical use, with the aid of novel particle engineering techniques and well established animal models to evaluate the bioavailability.

The use of nanotechnologies in commercial applications is increasing in many scientific disciplines. Chapter 1 reviews the unique size-controlled properties of nanomaterials, their disposition in the body after inhalation, and the factors influencing the fate of inhaled nanomaterials. The physiology of the lung makes it an ideal target organ for non-invasive local and systemic drug delivery, especially for protein and poorly water-soluble drugs. The potential application of pulmonary delivery of nanoparticle formulations of poorly water-soluble drugs is promising.

To improve the bioavailability of itraconazole (ITZ), an extremely poorly water-soluble drug which suffers erratic absorption from oral formulations, a particle engineering process ultra-rapid freezing (URF) was utilized to produce nanoparticle formulation for pulmonary delivery in Chapter 2. Biocompatible and biodegradable excipients suitable for lung use were employed to make the nanostructured aggregates containing ITZ:mannitol:lecithin=1:0.5:0.2, w/w), i.e. URF-ITZ. In which ITZ was found to molecularly dispersed in the excipients as a solid solution with high surface area and ability to achieve high magnitude of supersaturation. Aqueous colloidal dispersion of URF-ITZ was suitable for nebulization, which demonstrated optimal aerodynamic properties for deep lung delivery. Single dose inhalation of the nebulized aerosols in mice using a whole body exposure dosing apparatus demonstrated high lung and systemic ITZ levels.

The significantly improved systemic bioavailability of inhaled URF-ITZ was mainly ascribed to the amorphous morphology that raised the drug dissolution rate and saturation solubility. To evaluate the impact of supersaturation of amorphous relative to crystalline nanoparticulate formulations of ITZ on bioavailability via inhalation, a nano-sized crystalline ITZ composition was made by wet milling process (i.e. Wet-milled ITZ) to compare the bioavailability with URF-ITZ following inhalation in Chapter 3. Dissolution tests revealed that URF-ITZ achieved 4.7-times higher extent of supersaturation than nanocrystalline Wet-milled ITZ. This was translated to 3.8-times higher systemic ITZ levels in rats following a single dose inhalation of the respective nebulized aerosols using a nose-only dosing apparatus. Engineering amorphous nanoparticles of ITZ through pulmonary delivery is beneficial to improve therapeutic effects.

In Chapter 4, a 2-hydroxypropyl- $\beta$ -cyclodextrin (HP $\beta$ CD) solubilized ITZ solution (i.e., HP $\beta$ CD-ITZ) suitable for pulmonary delivery by nebulization was made, to compare pharmacokinetics of inhaled nebulized aerosols of HP $\beta$ CD-ITZ versus URF-ITZ, under the hypothesis that solubilized ITZ could be absorbed faster through a mucosal membrane than the nanoparticulate ITZ. Single dose inhalation of nebulized aerosols of HP $\beta$ CD-ITZ solution and aqueous colloidal dispersion of URF-ITZ in mice produced similar ITZ lung depositions, but significantly faster systemic absorption of HP $\beta$ CD-ITZ across lung epithelium than URF-ITZ. The faster absorption of solubilized ITZ across the lung mucosal surface may be due in part to the elimination of the phase-to-phase transition. However, the nanoparticle URF-ITZ offered higher systemic bioavailability due to the absorption enhancer, lecithin, contained in the formulation.

Table 1.1. Unique features of nanomaterials [16]

---

Size: 20-50 nm enters CNS
< 70 nm, able to escape defense system in vivo
High Surface to mass ratio
High strength, conductivity, solubility, durability and reactivity
Catalytic promotion of reactions
Ability to adsorb and carry other compounds
Ability to escape defense system in vivo
Ability to cross cellular and sub-cellular membranes
Surface coating (e.g. lecithin,albumin)
-Enhance uptake by Type I/II pneumocytes
-Transcytosis across capillary
Charged particle (higher inhaled deposition)

---

Table 1.2. Mechanism of Aerosol Deposition [23, 33]

Site	Size ( $\mu\text{m}$ )	Mechanism	Comment
Large airways	5-9 (slow inhalation) 3-6 (fast inhalation)	Impaction	Most deposition in Segmental airways
Smaller airways	1 - 5	Gravitational sedimentation	Improved with slow and deep breathe
Respiratory bronchioles	1 - 3	Gravitational sedimentation	Improved with slow and deep breathe
Alveoli	$\leq 0.5$	Brownian diffusion	Most exhaled

Figure 1.1. Relationship between particle size and number of molecules displayed on particle surface. The percentage of molecules displayed on the surface of the particles to the total molecules in the particles increases exponentially while particle diameter decreases in the range of 1-100 nm. At a particle diameter of 30 nm, about 10% of its molecules are displayed on the surface; whereas at 10 and 3 nm particle diameter, 20% and 50% of the total molecules in the particles may display on the surface, respectively. Increase the ratio of atoms or molecules on the surface to the total molecules of a material may enhance the chemical and biological properties of nanomaterials. The enhanced activities could be either beneficial (antioxidation, carrier capacity for drugs, increased uptake and interaction with biological tissues) or disadvantageous (toxicity, instability, induction of oxidative stress) depending on the intended use. Adapted from [4] with permission.

Figure 1.2. The effect of particle size on the deposition of aerosol particles in the human respiratory tract following a slow inhalation and a 5-second breath hold. Larger particles deposit in the airways or mouth and throat, whereas smaller particles deposit in the alveolar region. Particles  $<1 \mu\text{m}$  can be exhaled, thereby reducing deep-lung deposition. Reproduced from [36] with permission.

## **Chapter 2: High Bioavailability from Nebulized Itraconazole Nanoparticle Dispersions with Biocompatible Stabilizers**

### **2.1 ABSTRACT**

A nebulized dispersion of amorphous, high surface area, nano-structured aggregates of itraconazole (ITZ):mannitol:lecithin (1:0.5:0.2 w/w) yielded improved bioavailability in mice. The ultra-rapid freezing (URF) technique used to produce the nanoparticles was found to molecularly disperse the ITZ with the excipients as a solid solution. Upon addition to water, ITZ formed a colloidal dispersion suitable for nebulization, which demonstrated optimal aerodynamic properties for deep lung delivery and high lung and systemic levels when dosed to mice. The ITZ nanoparticles produced supersaturation levels 27 times the crystalline solubility upon dissolution in simulated lung fluid. A dissolution/permeation model indicated that the absorption of 3  $\mu\text{m}$  ITZ particles is limited by the dissolution rate (BCS Class II behavior), while absorption is permeation limited for more rapidly dissolving 230 nm particles. The predicted absorption half-life for 230 nm amorphous ITZ particles was only 15 min, as a result of the small particle size and high supersaturation, in general agreement with the *in vivo* results. Thus, bioavailability may be enhanced, by decreasing the particle size to accelerate dissolution and increasing permeation with (1) an amorphous morphology to raise the drug solubility, and (2) permeability enhancers.

### **2.2 INTRODUCTION**

Improving the bioavailability of active pharmaceutical ingredients (API), defined as the rate and extent of the API that reaches systemic circulation is a major goal of

pharmaceutical drug delivery. Enhancements in bioavailability may increase patient compliance. The effectiveness of poorly water soluble APIs can be severely limited when solubilities are too low to produce systemic therapeutic levels. Several strategies have been developed to improve the aqueous dissolution properties of poorly water soluble API formulations, including the use of surfactants, emulsification processes, solution based precipitation and solid state manipulation [1-6]. Amorphous particles may be designed to produce high levels of supersaturation relative to the solubility of the crystalline state [7]. Cryogenic technologies have been used to produce highly porous, amorphous, nanostructured particles with improved dissolution rates and high supersaturation drug levels relative to the solubility of the crystalline state for poorly water soluble APIs [8-10]. The Spray Freezing into Liquid (SFL) process forms a solid dispersion or solid solution composed of drug domains within a polymer matrix by spraying the drug/excipients solution directly into liquid nitrogen [8]. The URF particle engineering process utilizes rapid freezing of a drug/excipient solution onto a cryogenic substrate of desired thermal conductivity to obtain a solid dispersion/solution [10].

ITZ, a broad-spectrum antimycotic triazole has been used for both prophylaxis and treatment of invasive fungal diseases for the last two decades. ITZ is a poorly soluble weak base with a calculated  $\log P$  of 6.2. Its aqueous solubility is estimated at approximately 1 ng/mL at neutral pH and approximately 4  $\mu\text{g/mL}$  at pH 1 [11]. Given the high  $\log P$  value, ITZ is classified as a class II drug according to the Biopharmaceutical Classification System (BCS) [12]. Sporanox<sup>®</sup> oral capsule and solution, ITZ preparations for oral administration on the market, show low oral absorption and considerably varied pharmacokinetics in immunocompromised patients,[13-15]. To treat invasive fungal infection, especially *Aspergillus* spp. infections in immunocompromised patients, ITZ

levels of greater than 0.5 µg/g of lung tissue, or 0.5 µg/mL of blood [16] is generally required.

The design of rapidly dissolving drug nanoparticles offers potential improvements in therapeutic efficacy, stability, patient compliance, and safety [17, 18]. The route of administration is as important as the drug formulation for achieving therapeutic success [19-22]. Pulmonary delivery of a wide spectrum of drug substances, including proteins/peptides, nucleic acids, and antibiotics to the lungs can be highly effective for localized treatment or prophylaxis of pulmonary diseases, including lung infections, cystic fibrosis, and asthma [23]. Pulmonary delivery is a non-invasive route that facilitates deposition of large drug doses to the lungs, and offers the potential for high systemic absorption. Efficient systemic absorption is attributed to the lung's large absorptive surface area, very thin diffusion path to the blood stream, elevated blood flow, relatively low metabolic activity, and the avoidance of hepatic first pass metabolism [24]. Particle size distribution and morphology have pronounced effects on all aspects of pulmonary drug delivery, including deposition in the respiratory tract, dissolution in the lung lining fluid and the clearance mechanism [25]. The particle size of aerosols is determined by the inhalation device and physicochemical properties of the drug formulation, such as viscosity and surface tension [26].

Pulmonary drug delivery targeted to the alveoli is advantageous and critical for systemic absorption [27]. The concept of improving bioavailability of poorly water soluble APIs by pulmonary delivery of nanostructured aggregates has been recently reported in mouse models. Inhalation of a nebulized ITZ nanoparticle composition (ITZ:polysorbate 80:poloxamer 407 = 1:0.75:0.75 by weight ratio, prepared by SFL;

namely SFL-ITZ) by mice for 20 min produced relatively high drug concentrations in lung tissue and about one third the drug level in systemic circulation compared to Sporanox<sup>®</sup> solution administered orally at the same dose [28]. Nebulization of aqueous colloidal dispersions of amorphous cyclosporin A/polysorbate 80 nanoparticles into mice produced therapeutic lung levels and systemic concentrations below toxic limits [29].

Inclusion of certain surface active excipients in pulmonary formulations may enhance bioavailability, but may also interfere with cell lipid bilayer membranes and thus raise long term safety concerns [30]. The objective of this study was to develop an ITZ nanoparticle dispersion for pulmonary delivery by nebulization that does not require the use of synthetic polymers and surfactants to achieve high supersaturation values *in vitro* and high bioavailability. Mannitol is a widely used excipient approved by the Food and Drug Administration (FDA) for inhalation purposes [31, 32]. Lecithin, currently FDA approved for pulmonary formulations, contains mainly dipalmitoylphosphatidylcholine (DPPC), the primary component of endogenous human lung surfactant [33]. We hypothesize that a high surface area nanostructured ITZ composition encompassing soluble, and/or biodegradable, and/or biocompatible materials such as mannitol and lecithin, ITZ:mannitol:lecithin = 1:0.5:0.2 (by weight ratio, namely URF-ITZ), can be inhaled by nebulization to produce high supersaturation levels rapidly in the alveolar fluid. Pulmonary delivery of the nanostructured ITZ composition may provide not only local lung deposition, but possibly high systemic bioavailability with low toxicity.

The URF-ITZ dry powder and its aqueous dispersion suitable for nebulization were characterized by a wide variety of techniques. A single dose 24-hour pharmacokinetic study was also performed in mice to assess the bioavailability of

nebulized URF-ITZ nanoparticle dispersion by inhalation and to explore the factors influencing the pharmacokinetic parameters. In order to better understand how particle size and solubility (supersaturation) may be designed to enhance absorption rates in the alveoli, a recently developed model of Tam et al. [29] was used to analyze the individual effects of dissolution.

## **2.3 MATERIALS AND METHODS**

### **2.3.1 Materials**

The following materials were purchased: ITZ, micronized pharmacopeial grade (Hawkins Chemical, Minneapolis, MN); mannitol and polysorbate 80 (Spectrum Chemicals, Gardena, CA); lecithin, 1,4-dioxane (Fisher Scientific, Fair Lawn, NJ); diethanolamine (VWR International, West Chester, PA); acetonitrile (EM Industries Inc., Gibbstown, NJ). All organic solvents used were HPLC grade. Other reagents used were at least ACS grade.

### **2.3.2 Preparation of nanostructured aggregate powder of ITZ using URF technology**

For a standard batch of the formulation, lecithin (118 mg) was dissolved in a mixture of 1,4-dioxane and purified water (65/35, v/v) co-solvent system (200 mL) using a magnetic stirrer. ITZ (588 mg) and mannitol (294 mg) were subsequently dissolved in the mixture, this provided a dissolved solids ratio of ITZ:mannitol:lecithin of 1:0.5:0.2 by weight. The solution was frozen using the URF apparatus [10, 34]. Briefly, the solution was applied to the cryogenic solid substrate (which was previously cooled to -70 °C), whereby the solution was frozen rapidly. The resultant frozen solids were collected and lyophilized using a VirTis Advantage bench top tray lyophilizer (The VirTis Company,

Inc., Gardiner, NY, USA). The dry powder was stored in a desiccator under vacuum at room temperature.

### **2.3.3 Preparation of physical mixture**

A physical mixture consisting of ITZ:mannitol:lecithin in the weight ratio of 1:0.5:0.2 was mixed by geometric dilution and trituration using a ceramic mortar and pestle.

### **2.3.4 Powder X-Ray Diffraction (XRD)**

The URF-ITZ powder, the physical mixture, the bulk ITZ and mannitol were examined by wide angle XRD. A Philips 1710 X-ray diffractometer with a copper target ( $\text{CuK}\alpha 1, \lambda = 1.54056 \text{ \AA}$ ) and nickel filter (Philips Electronic Instruments Inc., Mahwah, NJ) was used to obtain the XRD patterns. The voltage was 40 kV and the current was 40 mA. Samples were analyzed in the 2-theta range from 10 to 50° using a step size of 0.05 2-theta degree with a dwell time of 2 sec.

### **2.3.5 Scanning Electron Microscopy (SEM)**

SEM was used to evaluate the morphology of the samples. The samples were mounted onto an aluminum stage using conductive carbon tape. Samples were coated using a model K575 sputter coater (Emitech Products, Inc., Houston, TX) with gold/palladium for 20 sec in a high vacuum evaporator. SEM was performed using a Hitachi S-4500 field emission scanning electron microscope (Hitachi High-Technologies Corp., Tokyo, Japan) operating at an accelerating voltage of 10-15 kV. Images were

captured with Quartz PCI software (Quartz Imaging Corporation, Vancouver, BC, Canada).

### **2.3.6 Scanning Transmission Electron Microscopy (STEM)**

The URF-ITZ powder was further characterized using STEM, by placing the dry powder on a Holey Carbon Support Film with 200 Mesh Copper Grids (Jed Pella, Inc., Redding, CA) and viewing on a JEOL 2010F transmission electron microscope (JEOL USA, Inc., Peabody, MA) equipped with an energy dispersive spectroscopy (EDS) detector for elemental characterization.

### **2.3.7 Thermal Analysis**

Differential Scanning Calorimetry (DSC) of the URF-ITZ powder and each component was conducted using modulated temperature DSC (MTDSC), Model 2920 (TA Instruments, New Castle, DE), equipped with a refrigerated cooling system. Dry nitrogen gas was used as the purge gas through the DSC cell at a flow rate of 40 mL/min. Samples were weighed to 10-15 mg in aluminum crimped pans, Kit 0219-0041 (Perkin-Elmer Instruments, Norwalk, CT). The mass of the empty sample pan was matched with that of the empty reference pan within  $\pm 0.2$  mg. Samples were heated at a ramp rate of 10 °C/min from -30 to 200 °C with a modulation temperature amplitude of 1 °C/60 sec for all studies. Data was analyzed using TA Universal Analysis 2000 software (TA Instruments, New Castle, DE). Amorphous pure ITZ was prepared by the URF process as described above. Amorphous mannitol and lecithin were prepared by quench-cooling [35]. In brief, accurately weighed mannitol and lecithin powders were heated to 200 and 150 °C, respectively, in sealed aluminum DSC pans, the temperature was held for 15 min.

The samples were then quench-cooled in liquid nitrogen externally to the DSC instrument. DSC was conducted by placing back the samples to pre-cooled sample chamber (-50 °C), and thermograms were recorded the same as with the other samples.

### **2.3.8 True Density Measurements**

True density of ITZ, mannitol and lecithin was measured using an AccuPyc 1330 helium pycnometer (Micrometrics; Norcross, GA). The samples were dried overnight. Upon measurement, the samples were purged 20 times with dry helium at 19.85 psi followed by six analytical runs at 19.85 psi. The equilibration rate was 0.0050 psi/min. Measurements were performed in triplicate.

### **2.3.9 Particle Size Analysis by Laser Diffraction**

Particle size distribution, based on volume fraction, of the URF-ITZ powder, the physical mixture and bulk ITZ was measured by laser diffraction with a Malvern Mastersizer-S (Malvern Instruments, Ltd., Worcestershire, UK). To measure the particle size distribution, powder aliquots were dispersed in 5 mL purified water, sonicated, and the dispersions were added to the sample reservoir to produce light obscuration in the range of 10–15%. Bulk ITZ was dispersed in 5 mL of a 0.1% polysorbate 80 aqueous solution for pre-wetting due to its high hydrophobicity. Sonication was used during the measurement to break up the agglomerated particles. Values reported are the average of at least three determinations.

### **2.3.10 Brunauer-Emmett-Teller (BET) Specific Surface Area Analysis**

Specific surface area was measured using a Nova 2000 version 6.11 instrument (Quantachrome Instruments, Boynton Beach, FL). An aliquot of powder was added to a 12-mm Quantachrome bulb sample cell and degassed overnight prior to analysis. The data was then analyzed using NOVA Enhanced Data Reduction Software (version 2.13).

### **2.3.11 Dissolution Testing at Supersaturation Conditions**

Dissolution testing at supersaturated conditions was conducted in a USP 25 dissolution apparatus model Vankel 7000 Dissolution Tester (Vankel Technology Group, Cary, NC) using 100 mL glass dissolution vessels and stirred with small paddles at 100 rpm. Simulated lung fluid containing 0.02% DPPC (Davies and Feddah, 2003, Cook et al., 2005) at 37 °C was used as the dissolution medium. An equivalent of 100 µg ITZ in a colloidal dispersion (equal to 100-times of equilibrium solubility of crystalline ITZ ( $C_{eq}$ )) at 4 °C was added to the dissolution vessels ( $n = 6$ ) within one second immediately after sonication. Aliquots of 2 mL of the dissolution media were taken at 5, 15, 30, 60, 120 and 180 min. All samples were filtered through a 0.2 µm GHP Acrodisc filter (Pall Corporation, East Hills, NY), and diluted with acetonitrile for content analysis. The ITZ content was determined using a Shimadzu LC-10A high performance liquid chromatography (HPLC) system (Shimadzu Corporation, Columbia, MD) equipped with an Alltech Inertsil<sup>TM</sup> ODS-2 5 µm, 150 mm × 4.6 mm, C-18 column (Alltech Associates, Inc., Deerfield, IL). The mobile phase was acetonitrile:water:diethanolamine (70:30:0.05) and it eluted the ITZ peak at approximately 5.5 min at 25 °C with a flow rate of 1 mL/min. The ITZ absorbance was measured at a wavelength  $\lambda_{max}$  of 263 nm.

### 2.3.12 In Vitro Aerosol Performance

A colloidal dispersion of the URF-ITZ powder was prepared for nebulization by dispersing the powder in purified water (equivalent to 20 mg/mL ITZ) using ultrasonication in an ice bath. An aliquot (5 mL) of the dispersion was nebulized using an Aeroneb® Professional micropump nebulizer (Nektar Inc., Mountain View, CA) for 10 min at an air flow rate of 28.3 L/min. The flow rate was maintained by a vacuum pump (MFG Corp., Benton Harbor, MI) and calibrated by a TSI mass flow meter, Model 4000 (TSI Inc., St. Paul, MN). The *in vitro* deposition characteristics of the colloidal dispersion of URF-ITZ for nebulization, was investigated using an eight-stage Andersen cascade impactor (Thermo-Electron Corp., Symrna, GA). The cascade impactor was assembled and operated in accordance with USP General Chapter 601 to assess the drug delivered. After deposition onto the stages of the impactor, the mass deposited on each of the stages was collected and the total mass of drug on each stage was analyzed by HPLC. The aerosolization behavior was described in terms of total emitted dose (TED), mass median aerodynamic diameter (MMAD), geometric standard deviation (GSD), and percentage fine particle fraction (FPF; defined as the percentage of droplets with an aerodynamic diameter less than 4.7  $\mu\text{m}$ ).

### 2.3.13 Stability Study

The URF-ITZ powder was stored in desiccators under vacuum at room temperature, and the physical stability was assessed by XRD at 1, 3 and 12 months.

The physical stability of the colloidal dispersion of URF-ITZ for nebulization was also investigated. The colloidal dispersion of URF-ITZ for nebulization was prepared as previously described. It was allowed to equilibrate at 25 °C for 15 min, and then was

quench frozen using excess liquid nitrogen. The colloidal dispersion was lyophilized, and the resultant powder was investigated by XRD.

#### **2.3.14 *In Vivo* Pulmonary Dosing of Mice**

Fourteen male ICR mice (Harlan Sprague Dawley, Inc., Indianapolis, IN) were dosed by inhalation of the nebulized colloidal dispersion of the URF-ITZ (equivalent to 20 mg/mL ITZ) for 10 min in a whole-body dosing chamber as previously described (McConville et al., 2005). This restraint-free chamber was designed to hold up to 14 mice. An Aeroneb Professional micropump nebulizer was situated at the inlet of the chamber, and the colloidal dispersion of the URF-ITZ was nebulized through the inlet into the chamber with an air flow rate of 1 L/min. Following exposure to the aerosol cloud, the mice were sacrificed by carbon dioxide asphyxiation at 0.5, 1, 2, 4, 6, 10, and 24 h time points post dosing. Blood samples were taken by cardiac puncture, and the lungs were harvested. The study protocol was approved and conducted in accordance with the Institutional Animal Care and Use Committee (IACUC) guidelines at The University of Texas at Austin.

#### **2.3.15 Plasma and Lung Analysis**

Serum was separated by centrifugation at 3,000 g for 10 min in a 1.5 mL micro-centrifuge tube using a Microfuge<sup>®</sup> 18 centrifuge (Beckman Coulter, Fullerton, CA). The serum and lung samples were stored at -20 °C until analyzed. The homogenized lung samples were prepared by adding 1 mL of normal saline to each of the harvested lung and homogenized using tip sonication on an ice bath. Drug levels in the calibration standards, serum and homogenized lung samples were analyzed as previously indicated [28].

Briefly, to an aliquot of 250  $\mu$ L serum or 250  $\mu$ L of lung homogenate, 50  $\mu$ L of 0.3 N barium hydroxide and 50  $\mu$ L of 0.4 N zinc sulfate heptahydrate solutions were added and vortex mixed for 30 sec to precipitate water-soluble proteins. Acetonitrile (1 mL) containing 500 ng/mL ketoconazole as an internal reference standard was added to each sample followed by vortex mixing for 1.5 min. Each sample was then centrifuged at 3,000 g for 15 min. The supernatant was transferred to a clean 1.5 mL micro-centrifuge tube and dried under a stream of nitrogen gas. Each sample was reconstituted with 250  $\mu$ L mobile phase (62% acetonitrile: 38% 0.05 M potassium phosphate monobasic buffer adjusted to pH 6.7 with NaOH) and analyzed by HPLC with an Alltech Inertsil<sup>TM</sup> ODS-2 5  $\mu$ m, 250 $\times$ 4.6 mm, C-18 column protected by a C-18 guard column (5  $\mu$ m, 7.5 $\times$ 4.6 mm) (Alltech Associates, Inc., Deerfield, IL). The injection volume was 100  $\mu$ L, and the wavelength of absorption was 263 nm ( $\lambda_{\text{max}}$ ). The limit of detection and quantitation for ITZ was 10 ng/mL and 30 ng/mL, respectively. The column was maintained at 37  $^{\circ}$ C during the analysis. The ITZ peak eluted at approximately 18 min and the ketoconazole peak eluted at 9.3 min at a mobile phase flow rate of 1.0 mL/min.

### 2.3.16 Pharmacokinetic Analysis

Pharmacokinetic parameters for lung and serum were derived by noncompartmental and one-compartmental analysis, respectively. Pharmacokinetic parameters were estimated by standard methods.  $C_{\text{max}}$  was the maximal concentration observed,  $T_{\text{max}}$  was the time to  $C_{\text{max}}$ , and they were obtained from the individual concentration-time curves. The  $K_{01}$  absorption and  $K_{10}$  elimination rate constants were determined by linear regression of the points of the log-linear plasma concentration versus time curve. The area-under-the-concentration-time curve from time zero to infinity ( $\text{AUC}_{0-\infty}$ ) was determined by use of the linear trapezoidal rule with extrapolation to

infinity by using the  $K_{10 \text{ elimination}}$  rate constant. The  $t_{1/2}$  was defined as  $0.693/\text{rate constant } K$  [36].

## 2.4 RESULTS

### 2.4.1 Physicochemical Properties of URF-ITZ Powder

The URF process was employed to make the nanostructured aggregate powder with an ITZ potency of 56%. ITZ is a highly crystalline hydrophobic molecule with a molecular weight of 705.64. The degree of crystallinity in the ITZ/excipient mixture has been shown to affect the solubility and dissolution rate of ITZ in the mixture [8]. The crystallinity of bulk ITZ, mannitol, URF-ITZ and the physical mixture were examined by XRD and the profiles are depicted in Figure. 1. The characteristic crystalline peaks for ITZ were found at 14.5, 17.6, 20.3, and 23.45 2-theta degrees, as seen in the bulk ITZ (purchased from the manufacturer) and physical mixture samples. The physical mixture of ITZ: mannitol: lecithin (1: 0.5: 0.2 ratio by weight) showed a qualitative reduction in crystalline intensity for both ITZ and mannitol. The URF-ITZ powder was amorphous as indicated by the absence of the characteristic crystalline peaks of ITZ and mannitol.

From the SEM images, the bulk ITZ and the physical mixture were composed of large, compact crystals at the micron-scale, ranging up to about 5  $\mu\text{m}$  in length (Figures 2.2a, 2.2b). In contrast, a highly porous structure with more regularly shaped particles of the URF-ITZ powder was observed at higher magnifications in Figures 2.2c and 2.2d, displaying aggregated nanoparticles that formed a porous matrix. Closer inspection of the morphology by STEM demonstrated that the bridged, round shaped primary particles of the nanostructured aggregates were about 30-50 nm in diameter, as seen in Figure 2.3a.

#### **2.4.2 Energy Dispersive Spectroscopy (EDS)---Elemental Characterization**

The ITZ molecule ( $C_{35}H_{38}Cl_2N_8O_4$ ) may be distinguished from other molecules present in the formulation due to the presence of two chlorine atoms; whereas mannitol contains only carbon, oxygen and hydrogen, and lecithin also contains phosphorus. Chlorine may be used as a marker to determine the distribution of ITZ molecules within the nanostructured aggregates. EDS was used to map the compositional distribution of the elements, including: carbon, oxygen and chlorine.

Elemental distribution mapping for carbon, oxygen and chlorine contained in the nanoparticle aggregates of URF-ITZ scanned by EDS are presented in Figure 2.3c, d, e along with a STEM image of the scanned nanostructured aggregates in Figure 2.3b. Element distribution images showed colored dots, representing the presence of a particular chemical element, in contrast to the black background. It can be seen that the distribution of each element is consistent with the shape and density of the aggregated nanoparticles scanned, including the presence of the pores.

#### **2.4.3 Thermal Analysis**

MTDSC was carried out to study the thermal properties of the URF-ITZ powder and its individual components. The glass transition temperature ( $T_g$ ) of URF pure ITZ (no excipients; 100% potency), quench-cooled mannitol and quench-cooled lecithin were 59.6 °C (consistent with reports of [37, 38], 16.8 °C and 5.1 °C, respectively, as shown in Figure 2.4 thermograms. The URF-ITZ powder (ITZ:mannitol:lecithin=1:0.5:0.2 ratio by weight) showed a single  $T_g$  at 44.5 °C. The corresponding physical mixture only showed

one endothermic melting peak at 166.2 °C. XRD was conducted on powders of the following compositions, and the results indicated that the URF pure ITZ (no excipients; 100% potency) was amorphous, URF pure mannitol was crystalline, URF pure lecithin was amorphous, URF ITZ:mannitol = 1:0.5 (ratio by weight) was amorphous, and URF mannitol:lecithin = 0.5:0.2 (ratio by weight) was partially crystalline (Figure 2.1).

#### **2.4.4 Particle Size Distribution**

The particle size distributions that measured by laser diffraction are shown in Table 2.1. The URF-ITZ powder showed a narrow size range with D<sub>50</sub> and D<sub>90</sub> (diameter at which the cumulative sample volume was under 50% and 90%, respectively) are less than 230 and 540 nm, respectively, compared to the corresponding values of 2.75 and 5.10 µm in the corresponding physical mixture.

#### **2.4.5 Specific Surface Area and True Density**

The specific surface area of the URF-ITZ powder was 71.48 m<sup>2</sup>/g, in contrast to 2.20 m<sup>2</sup>/g for the unprocessed bulk ITZ and 1.80 m<sup>2</sup>/g for the physical mixture. The URF process rendered the ITZ/excipients about 30-40 times greater surface area as compared to that of the bulk ITZ and the physical mixture, as seen in Table 2.1.

True density of ITZ, mannitol and lecithin were determined to be 1.37, 1.50, 1.10 g/cm<sup>3</sup>, respectively, by helium pycnometry.

#### 2.4.6 Supersaturation Dissolution Study

The maximum concentration of dissolved ITZ in simulated lung fluid was determined under supersaturated conditions (100-times  $C_{eq}$ ). The results are shown in Figure 2.5. The  $C_{eq}$  in simulated lung fluid was about 10 ng/mL after shaking at 37 °C for 3 days with excess ITZ present. The URF-ITZ powder showed a value of the measured concentration of dissolved ITZ ( $C$ ) versus  $C_{eq}$  ( $C/C_{eq}$ ) of 22-times at 5 min in simulated lung fluid and the highest value of 27-times at 15 min. The supersaturated ITZ concentration gradually decreased to about 7-times at 3 h. The physical mixture demonstrated about 2-times the measured  $C/C_{eq}$  at 15 and 30 min, and gradually decreased and reached a plateau at  $C_{eq}$  value after 2 h in the simulated lung fluid. The cumulative extent of supersaturation was calculated as the area-under-the-supersaturation-curve (AUSC), which was 25,000 and 2,500 ng·min/mL for URF-ITZ and the corresponding physical mixture, respectively.

#### 2.4.7 In Vitro Aerosol Performance

The aerodynamic particle size of the colloidal dispersion of URF-ITZ for nebulization, with an equivalent of 100 mg ITZ in 5 mL, is summarized in Table 2.2. The TED was 52.97 mg out of 100 mg ITZ available for nebulization. The FPF was 66.96% with a fine particle dose (amount of aerosol droplets entering the impactor less than 4.7  $\mu$ m,  $TED \times FPF$ , indication of the dose delivered to the deep lung) delivered at a rate of 3.55 mg/min. The MMAD of the atomized droplets was 2.38  $\mu$ m with a GSD of 2.56, which is suitable for deep lung delivery.

#### 2.4.8 Stability Study

The crystallinity of the URF-ITZ powder was monitored using XRD and the results are depicted in Figure 2.1. There was no characteristic crystalline peak of ITZ or mannitol detected by XRD after storage for up to 12 months, indicating the powder retained its amorphous morphology when stored at room temperature and protected from humidity.

Additionally as a simulation for the period of the URF-ITZ powder dispersion to be nebulized, the absence of characteristic crystalline peaks confirmed that the URF-ITZ in the colloidal dispersion remained amorphous over the nebulization time period.

#### 2.4.9 Single Dose, 24-h Pharmacokinetic Study in Mice

Mice inhaled the single dose aerosols of the nebulized URF-ITZ colloidal dispersion for 10 min. ITZ concentrations versus time in the blood and lung samples of the single dose 24-h pharmacokinetic study are presented in Figure 2.6. The pharmacokinetic parameters are listed in Table 2.3. In the lung samples, the  $C_{\max}$  was 21.19  $\mu\text{g/g}$  (wet lung tissue) at 0.5 h post dosing. The  $t_{1/2}$  was 7.4 h and the  $K_{\text{elimination}}$  rate constant was  $0.093 \text{ h}^{-1}$ , which may explain the ITZ lung level was maintained at 2.16  $\mu\text{g/g}$  (wet lung weight) for up to 24 h. In serum, based on a one-compartmental analysis, the  $C_{\max}$  was 1.64  $\mu\text{g/mL}$  at 2 h after dosing. The  $K_{01}$  absorption and  $K_{10}$  elimination rate constants were 0.757 and  $0.195 \text{ h}^{-1}$ , respectively. The  $t_{1/2 \text{ } k_{01}}$  and  $t_{1/2 \text{ } k_{10}}$  were 0.92 and 3.55 h, respectively.

## 2.5 DISCUSSION

### 2.5.1 Characterization of URF-ITZ and Comparison to SFL-ITZ

Pulmonary delivery of the nebulized colloidal dispersion of nanostructured aggregates of URF-ITZ dramatically improved bioavailability compared to the previously reported formulation of SFL-ITZ, more specifically a faster absorption rate, shorter  $T_{\max}$ , almost double the  $C_{\max}$  in lung tissue, and 10-times higher  $C_{\max}$  in blood were observed [28]. Both of the formulations were tested in the same animal model according to identical dosing apparatus and procedures. Further work would be needed to characterize the *in vitro* properties of the SFL-ITZ dispersions in order to understand these differences in bioavailability.

Both SFL and URF processes were able to create submicron particles of drug domains within a polymer matrix due to rapid freezing of a co-dissolved drug and excipient mixture [8, 9, 39]. Solid dispersions are systems in which drug particles are homogeneously distributed throughout a solid matrix. A solid solution results when the drug is molecularly dispersed throughout a solid matrix [40]; here, the particle size of the drug has been reduced to its absolute minimum without any crystalline drug domains [41]. Solid dispersions or solid solutions of poorly water soluble drugs have greatly enhanced extents and rates of dissolution, due to increased exposure area of drug to the dissolution media and higher Gibbs free energy of the amorphous versus crystalline states [6, 42]. This leads to significantly improved bioavailability and therefore is of interest to pharmaceutical formulation scientists.

In this study, powder XRD, MTDSC and EDS were used to differentiate between a solid dispersion and solid solution. Based on the MTDSC results, a single  $T_g$  for the

URF-ITZ powder was observed between the  $T_g$ s of the amorphous pure ITZ and mannitol. The modified Gordon–Taylor equation for ternary systems [43] was used to predict the  $T_g$  of the URF-ITZ powder:

$$T_g = \frac{w_1 T_{g1} + K_1 w_2 T_{g2} + K_2 w_3 T_{g3}}{w_1 + K_1 w_2 + K_2 w_3} \quad (1)$$

where  $w_1$ ,  $w_2$ , and  $w_3$  are the weight fractions of lecithin, mannitol and ITZ, respectively, and  $T_{g1}$ ,  $T_{g2}$  and  $T_{g3}$  are the corresponding glass transition temperatures.  $K$  is a constant calculated by

$$K_1 = \rho_1 T_{g1} / \rho_2 T_{g2}, K_2 = \rho_2 T_{g2} / \rho_3 T_{g3} \quad (2)$$

where  $\rho_1$ ,  $\rho_2$ , and  $\rho_3$  are the corresponding true densities. The predicted  $T_g$  of 42.3 °C, agrees closely with the measured  $T_g$  of 44.5 °C for the URF-ITZ powder.

The XRD pattern indicated that URF processed pure mannitol was partially crystalline; whereas ITZ:mannitol=1:0.5 and ITZ:mannitol:lecithin=1:0.5:0.2 (URF-ITZ) were completely amorphous. Absence of crystallinity of the drug or complete absence of a drug peak (either in DSC or XRD) indicates that the composition is a solid solution [44]. The partial crystallization of the mannitol by URF and lyophilization may be expected from its low  $T_g$  of 16.8 °C. Kim et al. also reported similar results and difficulty in obtaining amorphous mannitol freeze-dried powder [35]. ITZ may retard mannitol crystallization from the glassy state, which is expected from a miscible polymer pair. Lecithin itself is in an amorphous form. Mannitol and lecithin may plasticize the extremely hydrophobic ITZ in the URF-ITZ powder leading to improved wettability, though also reduction of its  $T_g$ .

Moreover, EDS was performed to analyze the distribution of ITZ in the drug/excipient matrix by mapping elemental distributions. Theoretically, the ratios of the main elements (carbon, oxygen, chlorine) at any given area should be constant if ITZ, mannitol and lecithin formed a solid solution. EDS is capable of highly selective spatial resolution of chemistry, from volumes as small as  $1\ \mu\text{m}^3$  [45]. The qualitative elemental distribution images suggest a generally homogenous distribution of ITZ in the scanned aggregated nanoparticles of URF-ITZ. Based on MTDSC, XRD, and EDS results, the components of the URF-ITZ composition are fully miscible and dispersed in each other at the molecular level. Thus, the URF-ITZ powder is primarily a solid solution formed by the immobilization of molecularly dispersed ITZ and excipients (mannitol, lecithin) on a timescale of milliseconds during the URF process [10, 46].

### **2.5.2 Role of the surfactant and mannitol**

In the URF-ITZ composition, the soy lecithin is an accepted excipient for aerosol inhalation [32]. It is acceptable in the lung as the biocompatible and biodegradable substance, *i.e.* phosphatidylcholine (PC) comprises an estimated 70-80% of the naturally occurring pulmonary surfactant pool [47]. Besides playing an important role in improving the wettability of the nanoparticles containing ITZ, it may also enhance the absorption of ITZ across the lung epithelium. Phospholipids are known to penetrate cell membranes, decrease bilayer stability, and thereby induce changes in the cytoskeleton that can affect tight junctions and accelerate paracellular passage of drugs [48-50]. Codrons et al. [51] reported that incorporation of DPPC into a dry powder formulation of parathyroid hormone for pulmonary administration produced a high systemic bioavailability of 34% in rats. DPPC has also been shown to increase absorption of insulin via pulmonary delivery and enhance the hypoglycemic effect in rats relative to free insulin, when

formulated as an admixture or in liposomes [52, 53]. The addition of very small amounts of exogenous DPPC may transiently alter local PC concentrations [54], and/or accelerate the surfactant turnover process, leading to enhanced penetration of the drug molecules through the lung alveolar cells into the systemic circulation [52].

In the present study, the high systemic absorption of ITZ following pulmonary dosing may be attributed partially to the inhaled exogenous PC, as well as the small particle size. The PC from lecithin may facilitate both dissolution and permeation, via dilated pulmonary epithelial tight junctions. Thus, the selection of lecithin as an excipient in the URF-ITZ composition offers the potential of marked improvement in absorption, without adding toxicity to the formulation. Moreover, the presence of the surfactant in the ITZ nanoparticle formulations is important to stabilize the dispersion and aid in wetting upon deposition in the lungs. Nanoparticles have high surface energies, due to the high surface-to-volume ratio and tend to agglomerate. Wettability of the URF-ITZ powder is critical for forming dispersions in the aqueous medium prior to nebulization. Mannitol was chosen as the second excipient in the URF-ITZ composition, to improve wetting of the URF-ITZ powder by introducing water into the matrix to aid dissolution.

Once the drug is deposited in the aqueous lining fluid in the lung, the mannitol may quickly dissolve, resulting in a porous drug matrix. Lecithin will initially swell, causing stress relaxation of the matrix and allowing water ingress before it dissolves. These processes will help stabilize the ITZ from aggregation and precipitation during dissolution.

The URF process dramatically increased the surface area of the nanostructured aggregates of URF-ITZ to about 40 times that of the corresponding physical mixture for

dissolution. Additionally, the thinner diffusion boundary layer for the smaller particle size raises the dissolution rate [55, 56]. Furthermore, the degree of crystallization of undissolved ITZ in the particles upon exposure to the lung fluid is reduced by the rapid dissolution of the high surface area nanoparticles relative to microparticles, as examined in detail elsewhere [6]. A combination of increased intrinsic solubility and reduced chance to crystallize of undissolved ITZ in the media may provide an explanation for the URF-ITZ to produce supersaturation values more than 20-times  $C_{eq}$  in simulated lung fluid.

### 2.5.3 Deposition of the nanoparticles containing ITZ

It is generally accepted that aerosol droplets with aerodynamic diameters between 1-5  $\mu\text{m}$  can be delivered into the alveolar lumen after inhalation [57]. Furthermore, the aerosol diameter of aqueous droplets produced by nebulizers may readily be tuned to this optimal size range [27]. Nanoparticles may be distributed more uniformly throughout the nebulized droplets than microparticles [58, 59]. For instance, if the volume fraction,  $f$ , of particles in the solvent is 0.01, then only about 1/100 of 3  $\mu\text{m}$  carrier droplets will contain a 3  $\mu\text{m}$  particle. In contrast each carrier droplet would contain about twenty-two 230 nm particles according to the relationship:

$$N_{\text{particles}}/N_{\text{drops}} = f \frac{r_{\text{drop}}^3}{r_{\text{particle}}^3} \quad (3)$$

Thus, the rate of drug absorption may be increased for nanoparticle relative to microparticle colloidal dispersions, by promoting more uniform drug distribution throughout the alveoli [60, 61]. More specifically, for a 32.5  $\mu\text{g}$  drug/g lung dose (chosen based on the ITZ  $C_{\text{max}}$  recovered from lung tissue at  $t=0.5$  h and the corresponding blood concentration given in Figure 2.6.) delivered as 3  $\mu\text{m}$  drug particles, only 1 in 75 alveoli

are estimated to receive a particle. However, approximately 30 drug particles are deposited in each alveolus when the same dose is delivered as 230 nm drug particles.

#### **2.5.4 Absorption of ITZ as a function of the composition and particle morphology**

A drug in an amorphous state will possess a higher intrinsic solubility than in its crystalline state [6, 62-64]. The URF-ITZ powder was shown to be an amorphous solid solution by DSC, XRD, and elemental mapping analysis. Furthermore, the exposure of ITZ molecules to the dissolution medium is maximized in the high surface area particles, as the soluble mannitol and lecithin dissolve in the lung lining fluid. The dispersed ITZ molecules are then available as free molecules to form a supersaturated solution [41]. After deposition of the inhaled ITZ nanoparticles in the lung lining fluid, the rate and extent of dissolution influence the permeation rate of ITZ through the lung epithelium to reach systemic circulation.

The effects of particle size, dissolution rate, extent of supersaturation and permeability on absorption of poorly water soluble drugs in the lungs were examined with a model reported recently [29]. The Noyes-Whitney equation describes the dissolution rate of ITZ spherical nanoparticles. The permeate concentration was assumed to be zero as the drug concentration in the blood may be assumed to be insignificant compared to that in the alveolar fluid and thus the permeation is irreversible [65]. The thickness of the human alveolar membrane (100-200 nm) is small versus the diameter of the alveolus (300  $\mu\text{m}$ ) [27, 66] and thus planar coordinates are appropriate. Consider a material balance on the fluid surrounding a drug particle in the alveolar fluid as shown in Figure 2.7. The accumulation of dissolved drug in the fluid of a single alveolus C is given

by the inlet flow from particle dissolution and the depletion by an outlet flow from drug permeation through the epithelium [29]

$$\frac{\partial C}{\partial t} = N_p D \frac{2\pi r}{V} (C_{\text{sat}} - C) - \frac{AP}{V} C \quad (4)$$

where  $N_p$  is the number of drug particles deposited in each alveolus,  $D$  is the diffusion coefficient of the drug,  $P$  is the permeability, and  $V$  and  $A$  are the volume and surface area, respectively, of an annular layer of lung fluid in a single alveolus adjacent to the epithelium (Figure 2.7.). Absorption half-lives were determined as the time when  $M_{\text{permeated}}/M_0 = 0.5$  or likewise,  $r^3/r_0^3 = 0.5$ . It is instructive to consider the two boundary conditions for absorption: purely dissolution limited and purely permeation limited. For purely dissolution limited absorption ( $P = \infty$  and  $C \rightarrow 0$ ), the absorption half-life becomes

$$t_{50} \approx \frac{0.37r_0^2}{DC_{\text{sat}}} \rho \quad (5)$$

and for purely permeation limited absorption (dissolution rate  $\rightarrow \infty$  and  $C=C_{\text{sat}}$ )

$$t_{50} = \frac{0.5M_0}{A_{\text{Alv}}PC_{\text{sat}}} \quad (6)$$

where  $A_{\text{Alv}} = A$  for planar geometry.

The Wilke-Chang equation was used to estimate a  $D = 5.26 \times 10^{-6} \text{ cm}^2/\text{s}$  [67] for ITZ. A  $P$  value of  $5.61 \times 10^{-5} \text{ cm/s}$  was chosen based on experimental ITZ permeabilities in intestinal membranes [68]. Common permeabilities of poorly water soluble drugs with similar molecular sizes in lung cell cultures range between  $10^{-6}$ - $10^{-4} \text{ cm/s}$  [69]. The number of drug particles deposited in the lungs was calculated from an estimated drug dose and the average particle volume. The drug dose, or the total mass of drug deposited in the lungs, was approximated to be  $5.8 \mu\text{g}$  ( $32.5 \mu\text{g/g}$  wet lung tissue) based on the lung tissue  $C_{\text{max}}$  ( $21.2 \mu\text{g/g}$ ) and the corresponding blood concentration ( $492 \text{ ng/mL}$ ) from the

single-dose pharmacokinetic study. The number of alveoli in a mouse was estimated to be  $\sim 2.25 \times 10^7$ , calculated using an alveolar surface area of  $680 \text{ cm}^2$  [70] and alveolus diameter of  $31 \text{ }\mu\text{m}$  [71] for mice. Total alveolar fluid volume was estimated to be  $8.3 \text{ }\mu\text{L}$ , based on a human alveolar surface fluid volume of  $15 \text{ mL}$  [66, 72] and the ratio of human lung to mouse lung weight.

Figure 2.8. shows the predicted absorption half-lives for particles ranging from  $50 \text{ nm}$  to  $3 \text{ }\mu\text{m}$  in diameter for a wide equilibrium solubility range, from  $10 \text{ ng/mL}$  to  $10 \text{ }\mu\text{g/mL}$ . Particle sizes between  $50\text{-}230 \text{ nm}$  are representative of URF-ITZ particles, as determined by STEM images (Figure 2.3a) and light scattering results (Table 2.1.), whereas a particle size of  $3 \text{ }\mu\text{m}$  is typical of particles traditionally delivered to the lungs (Courrier et al., 2002). The  $t_{50}$  for a crystalline  $3 \text{ micron}$  ITZ particle ( $C_{\text{sat}}=10 \text{ ng/mL}$ ) was estimated to be  $200 \text{ h}$  (Figure 2.8G), far too slow to be appropriate for therapy. In contrast,  $t_{50}$  values for the amorphous  $230 \text{ nm}$  particles were only  $14.7 \text{ min}$ , which would be consistent with the kinetics for the studies with mice in Figure 2.6.

The  $t_{50}$  values are shown for purely dissolution limited absorption (diamonds, infinite permeability) and purely permeation limited absorption (asterisks,  $C = C_{\text{sat}}$ ). For permeation limited absorption,  $t_{50}$  does not change with particle size for the  $50$  and  $230 \text{ nm}$  particles as predicted from eq. 6. However, it is much larger for a  $3 \text{ }\mu\text{m}$  particle deposited in an alveolus because of the larger  $M_0$ . Based on *in-vivo* lung and blood levels, only 1 in 67 alveoli would be estimated to receive a  $3 \text{ }\mu\text{m}$  drug particle compared to about 30 particles per alveolus for a  $230 \text{ nm}$  particle. For the  $230 \text{ nm}$  particles, the smaller  $M_0$  resulting from the more uniform distribution of particles throughout all of the alveoli is a major benefit, as it produces smaller  $t_{50}$  values relative to microparticles.

For all three  $C_{\text{sat}}$  values with 3  $\mu\text{m}$  particles, the absorption rate is strongly limited by the dissolution rate as expected for a BCS Class II drug. Thus, the  $t_{50}$  decreases orders of magnitude with an increase in  $C_{\text{sat}}$  by 1000 fold, which increases the driving force for particle dissolution. Interestingly, the absorption became much more permeability limited than dissolution rate limited for the 230 nm particles, no longer exhibiting BCS Class II behavior, for all three  $C_{\text{sat}}$  values. For the high surface area 50 nm particles, the dissolution rate limited  $t_{50}$  was about two orders of magnitude shorter than the permeation limited value. With the extremely rapid dissolution rates relative to permeation, absorption times remained fairly constant versus particle diameter for sub-230 nm particles, at a given equilibrium solubility (Figure 2.8A-F).

Despite the high dissolution rate for the 230 nm crystalline particles, the  $t_{50}$  value was still undesirably long because of the effect of the low  $C_{\text{sat}}$  on the permeability. The  $t_{50}$  was reduced markedly by an increase in  $C_{\text{sat}}$  for the amorphous URF-ITZ. Yet a further improvement in permeation rates may be achieved by incorporating permeability enhancers. In fact, the increased systemic absorption rate of URF-ITZ over SFL-ITZ [28], despite the similar particle sizes, may be explained by the incorporation of lecithin in the URF-ITZ formulation, a known permeation enhancer. As a result, an order of magnitude increase in  $C_{\text{max}}$  was achieved in circulation (URF-ITZ: 1.64  $\mu\text{g/mL}$  serum versus SFL-ITZ: 0.12  $\mu\text{g/mL}$ ) in a shorter time ( $T_{\text{max}}$  of URF-ITZ: 2 h versus SFL-ITZ: 5.35 h) as well as a higher absorption rate of ITZ from lung to blood compared to the SFL-ITZ formulation (URF-ITZ: 0.757  $\text{h}^{-1}$  versus SFL-ITZ: 0.186  $\text{h}^{-1}$ ) [9].

## 2.6 CONCLUSIONS

Amorphous ITZ particles were made by the ultra-rapid freezing process with FDA approved biodegradable and biocompatible excipients to achieve a mean diameter of 230 nm, a large surface area of 71 m<sup>2</sup>/g, and a wettable surface. The particles dissolved rapidly in simulated lung fluid to produce supersaturation levels up to 27-times of  $C_{eq}$  for the crystalline form. Nebulized aqueous colloidal dispersions of the ITZ nanoparticles exhibited aerodynamic characteristics suitable for deep lung delivery. An *in vivo* single dose 24-h pharmacokinetics study of the nebulized ITZ nanoparticle dispersion demonstrated substantial lung deposition and systemic absorption with blood levels reaching a peak of 1.6 µg/mL serum in 2 h.

To investigate the mechanism of drug absorption in the alveolar epithelium, a dissolution/permeation model was used to elucidate the effects of particle size and solubility. ITZ microparticles (3 µm) exhibited BCS Class II behavior for poorly soluble drugs with high permeabilities, where the absorption was influenced strongly by the dissolution rate. However, for 230 nm particles, the dissolution became sufficiently fast such that the concentration in the alveolar fluid reached saturation, and consequently, the absorption became permeation limited. Therefore, a microparticle formulation with BCS Class II behavior, may exhibit a completely different kind of behavior when reformulated at the nanoscale.

Four strategies were used to raise the bioavailability. The aqueous nebulized droplets were optimized to deposit the drug in the deep lungs. The decrease in particle size (increase in surface area) enhanced the dissolution rate as well as the uniformity of the distribution of drug dose among the alveoli. The increase in  $C_{sat}$  with the formation of

an amorphous polymorph, raised the driving force for permeation through the alveolar membrane. The fourth and final approach was to raise the membrane flux with lecithin, a known permeation enhancer. For the permeation limited absorption of the 50-230 nm URF-ITZ nanoparticles, the presence of lecithin may have contributed to the enhanced systemic levels observed in the *in-vivo* results. Pulmonary delivery of the ITZ nanoparticle aerosols offers the potential to treat invasive fungal infections more effectively in patient populations that have poor prognosis.

## 2.7 ACKNOWLEDGEMENTS

The authors are grateful to Dr. Troy Purvis for his help with HPLC analysis. The values are also shown for purely dissolution limited absorption (diamonds, infinite permeability) and purely permeation limited absorption (asterisks,  $C = C_{sat}$ ).

### **Chapter 3: Comparison of the Bioavailability of Amorphous versus Crystalline Itraconazole Nanoparticles via Pulmonary Administration in Rats**

#### **3.1 ABSTRACT**

The effect of supersaturation on bioavailability of inhaled nebulized aerosols is compared for amorphous versus crystalline nanoparticulate dispersions. The nanocrystalline formulations of itraconazole (ITZ) were made using wet milling (*i.e.* Wet-milled ITZ), whereas nano-structured aggregates (ITZ:mannitol:lecithin =1:0.5:0.2, weight ratio) were made using an ultra-rapid freezing process (*i.e.* URF-ITZ). Dissolution tests revealed the extent of supersaturation was 4.7-times higher for URF-ITZ versus Wet-milled ITZ, though their dissolution rates were similar. The aerodynamic performances of both aqueous colloidal dispersions were comparable and suitable for deep lung delivery. Single-dose 24-hr pharmacokinetic studies were conducted in Sprague-Dawley rats following inhalation of the nebulized colloidal dispersions (equivalent to 20 mg ITZ/mL dispersion in 5 mL) using a nose-only dosing apparatus. Lung depositions following inhalation were similar for both compositions. In systemic circulation, Wet-milled ITZ and URF-ITZ achieved  $C_{\max}$  of 50.4 and 177.5 ng/mL at 2.7 and 4 hr, and  $AUC_{0-24}$  of 662 and 2543 ng·hr/mL, respectively, based on one-compartmental analysis. Pulmonary delivery of the nanoparticulate amorphous ITZ composition resulted in significantly higher systemic bioavailability than for the nanocrystalline ITZ composition, as a result of the higher supersaturation that increased the permeation of ITZ.

## 3.2 INTRODUCTION

Modern drug discovery processes, which routinely use high throughput screening techniques, appear to result in a higher prevalence of lead compounds with increased molecular weight and lipophilicity [1, 2]. Such drug molecules pose challenges to formulate therapeutically effective products for clinical use, since they often have poor bioavailability issues due to their poor dissolution or poor permeability to achieve sufficient and consistent systemic exposure. Consequently this results in sub-optimal efficacy in patients, particularly when delivered via the oral administration [3, 4].

To address the issues of low aqueous solubility, solubilization and micronization have commonly been used to increase dissolution rate and thereby oral bioavailability of such drugs. Attempts to solubilize and stabilize these drugs using salt formation [5], co-solvents [6], micellar solutions [7], or inclusion complexes with cyclodextrins [8] have been of limited success. The increased amount of excipients required to formulate the poorly water-soluble drugs may potentially increase side effects, resulting in low patient compliance. Alternatively, invasive dosage forms such as parenteral formulations have to be developed to address the challenges being presented. However, with even less pharmaceutically acceptable excipient options, increased solubilization of drug is practically limited [9].

For the means of micronization, although particle size reduction of the poorly water-soluble drugs increases their dissolution rate by increasing drug surface area, it does not increase equilibrium solubility. Often for drugs with very low aqueous solubility, the achieved increase in dissolution rate is limited and insufficient to provide significant enhancement of bioavailability [3].

However, drug particles in the 100 nm range dissolve more quickly and to a greater extent (*i.e.*, higher equilibrium solubility) than micronized drug particles, as described by the Noyes-Whitney and Ostwald-Freundlich equations [10]. Both particle dissolution kinetics and solubility are size dependent. Thus, the dissolution of drug nanoparticles *in vivo* is usually accompanied by an increase in bioavailability [11, 12]. On the other hand, the potential for increased Van der Waals interactions and electrostatic attraction between ultrafine particles can reduce the effective surface area for dissolution and therefore counteract improvements in bioavailability [13]. Colloidal dispersions of drug nanocrystals with a typical mean particle size between 200 and 500 nm and stabilized by a suitable stabilizer (*i.e.* nanosuspension) [4], have therefore been developed as an alternative approach.

The effectiveness of nanosuspensions of poorly water-soluble drugs in enhancing bioavailability has been proved in animal models and clinical trials with various administration routes, including oral [14, 15], pulmonary [16-18], ocular [19, 20] and parenteral delivery due to their particle size sufficiently small to be injected intravenously [21-23]. Among these, of particular interest is inhalation delivery, because of the following advantages of this noninvasive delivery route: (1) potential for high systemic absorption with an enormous absorptive surface area of approximately 100 m<sup>2</sup>, very thin diffusion path to the blood stream and rich vasculature that facilitate rapid delivery of large drug doses; (2) targeted lung local action with reduced systemic side effects relative to other routes of administration, and (3) relatively low metabolic activity and avoidance of hepatic first-pass metabolism [24, 25].

Several studies predicted, from thermodynamics, the potential impact of polymorphs on bioavailability based on *in vitro* dissolution profiles and/or thermal analysis for oral delivery [26-28]. The amorphous form of a drug has a higher thermodynamic chemical potential than its crystalline counterpart [29]. The higher thermodynamic activity of the drug can produce supersaturated solutions [28, 30], thereby providing an opportunity to enhance absorption and bioavailability. In most experimental studies, supersaturation values of micron sized particles are less than 5-times  $C_{eq}$ , despite predictions from calorimetric measurements of the heat capacity (used to determine the free energy) that they can be much larger [26, 31]. Significantly higher supersaturation values approaching 100 were achieved for amorphous nanoparticles relative to microparticles, as the microparticles crystallize in the solid state before they dissolve and produce high supersaturation [32]. The experimental supersaturation values approached the large values calculated from the heat capacity glassy solid measured by DSC [28], unlike previous studies with microparticles where supersaturation values are typically below 5.

Amorphous nanostructured formulations of poorly water-soluble drugs for pulmonary delivery have also been developed to enhance therapeutic effectiveness [33, 34]. Vaughn et al. reported that inhaled aerosols in mice of a nebulized ITZ amorphous nanoparticulate composition (ITZ: polysorbate 80: poloxamer 407 = 1:0.75:0.75 by weight ratio, prepared by Spray Freezing into Liquid technology; namely SFL-ITZ) for 20 min, achieved a lung tissue  $C_{max}$  of 13.4  $\mu\text{g/g}$  wet lung weight and an  $\text{AUC}_{inf}$  of 99.7  $\mu\text{g}\cdot\text{hr/mL}$ , and a serum  $C_{max}$  of 0.12  $\mu\text{g/mL}$  [35]. Inhalation of another ITZ nanostructured composition (ITZ: poloxamer 407: polysorbate 80 = 1: 0.16: 0.13 by weight ratio, prepared by Evaporative Precipitation into Aqueous Solution technology;

namely EPAS-ITZ) which had a crystalline morphology, in the same mouse model produced a high lung  $C_{\max}$  of 16.8  $\mu\text{g/g}$  wet lung weight and an  $\text{AUC}_{\text{inf}}$  of 85.8  $\mu\text{g}\cdot\text{hr/mL}$ , but no systemic ITZ level was reported [36]. Despite the similar lung depositions of inhaled ITZ, in a subsequent prophylaxis study using a mouse model of invasive pulmonary aspergillosis, the nebulized aerosols of SFL-ITZ led to higher survival than for EPAS-ITZ for both short (8 days) and long-term survival (20 days) [37]. This improvement in survival may have resulted from a higher supersaturation of ITZ in the lung fluid for the amorphous SFL-ITZ, compared to crystalline EPAS-ITZ formulation.

To our knowledge, so far no study has assessed the effects of amorphous versus crystalline nanoparticulate formulations of a poorly water-soluble drug on *in vivo* bioavailability following lung delivery. In the present study, we evaluate the impact of the *in vitro* solubility advantage of amorphous versus crystalline nanoparticulate formulations of poorly water-soluble drug on bioavailability following pulmonary administration. We hypothesize that the supersaturation produced by inhaled amorphous nanoparticles of a poorly water-soluble drug will produce a higher systemic absorption and thereby enhanced bioavailability, relative to the nanocrystalline counterpart. ITZ was chosen as a model poorly water-soluble drug, because of its extremely high lipophilicity, *i.e.* an estimated aqueous solubility of about 1 ng/mL at neutral pH and a calculated octanol/water partition coefficient (Clog P) value of 6.2 [38]. A nano-sized crystalline ITZ composition was made by wet ball milling process (*i.e.* Wet-milled ITZ). The amorphous nano-structured aggregates of ITZ composition (ITZ: mannitol: lecithin = 1: 0.5: 0.2 by weight ratio) with a large, wettable surface made by ultra-rapid freezing process (*i.e.* URF-ITZ) was reported previously [34]. We compare both the physiochemical properties *in vitro* and the bioavailability after inhalation in rats. Given

that pulmonary delivery has become an increasingly attractive route of application for poorly water-soluble drugs, the ability to provide greater insight into formulation design for improved bioavailability will be of widespread interest.

### **3.3 MATERIALS AND METHODS**

#### **3.3.1 Materials**

The following materials were purchased: ITZ, micronized B.P. grade (Hawkins Chemical, Minneapolis, MN); mannitol and lecithin (Spectrum Chemicals, Gardena, CA); 1,4-dioxane and acetonitrile (Fisher Scientific, Fair Lawn, NJ); diethanolamine (VWR International, West Chester, PA). All organic solvents used were HPLC grade. Other reagents used were at least of ACS grade.

#### **3.3.2 Preparation of Crystalline ITZ Nanoparticulates and Amorphous Nanostructured Aggregate of ITZ**

The crystalline ITZ nanoparticulates were prepared by wet ball milling in a ceramic jar with Zirconia grinding media (1/2" Radius end cylinder) (U.S. Stoneware, East Palestine, OH). Three grams of the commercially available ITZ powder (mean particle size of 5  $\mu\text{m}$  in diameter, 100% < 17.7  $\mu\text{m}$ ) was added 15 mL of purified water and milled at 100 rpm 20 °C under nitrogen gas for 10 days. Thus obtained slurry was combined with several successive washings of the ceramic jar and milling media using purified water to make a dispersion of the milled ITZ; which was then quickly frozen by dripping into liquid nitrogen and lyophilized to obtain dry powder by using a VirTis Advantage bench top tray lyophilizer (The VirTis Company, Inc., Gardiner, NY, USA). Thus obtained Wet-milled ITZ dry powder was stored in a desiccator under vacuum (~15% relative humidity) at room temperature.

Amorphous nanostructured aggregate URF-ITZ powder was prepared using the ultra-rapid freezing (URF) technology, as described previously [34]. In brief, lecithin was dissolved in a mixture of 1, 4-dioxane and purified water (65/35, v/v) co-solvent system using a magnetic stirrer. Mannitol and ITZ were subsequently dissolved in the mixture, in a weight ratio of ITZ:mannitol:lecithin = 1:0.5:0.2. The solution was rapidly frozen after applied to the URF apparatus that pre-cooled to about  $-70^{\circ}\text{C}$  [39]. The frozen solids were collected, lyophilized and stored the same as described above.

### **3.3.3 Scanning Electron Microscopy (SEM)**

SEM was used to evaluate the morphology of the samples. The samples were mounted onto an aluminum stage using conductive carbon tape. Samples were coated using a model K575 sputter coater (Emitech Products, Inc., Houston, TX) with gold/palladium for 20 sec in a high vacuum evaporator. SEM was performed using a Hitachi S-4500 field emission scanning electron microscope (Hitachi High-Technologies Corp., Tokyo, Japan) operating at an accelerating voltage of 10-15 kV. Images were captured with Quartz PCI software (Quartz Imaging Corporation, Vancouver, BC, Canada).

### **3.3.4 Powder X-Ray Diffraction (XRD)**

The crystallinity of the dried powders of Wet-milled ITZ and URF-ITZ were examined by wide angle XRD. A Philips 1710 X-ray diffractometer with a copper target ( $\text{CuK}\alpha_1, \lambda = 1.54056 \text{ \AA}$ ) and nickel filter (Philips Electronic Instruments Inc., Mahwah, NJ) was used to obtain the XRD patterns. Dried powder was pressed onto a glass slide to

from a level surface. Samples were analyzed in the 2-theta range from 10 to 50° using a step size of 0.05 2-theta degree with a dwell time of 2 sec.

### **3.3.5 Modulated Temperature Differential Scanning Calorimetry (MTDSC)**

Thermal properties of the powder samples were investigated using a TA Instruments Model 2920 DSC (New Castle, DE), equipped with a refrigerated cooling system. Dry nitrogen gas was used as the purge gas through the DSC cell at a flow rate of 40 mL/min. Samples were weighed to 10-15 mg in aluminum crimped pans (Kit 0219-0041, Perkin-Elmer Instruments, Norwalk, CT). The mass of the empty sample pan was matched with that of the empty reference pan within  $\pm 0.2$  mg. Samples were heated at a ramp rate of 10 °C/min from 0 to 200 °C with a modulation temperature amplitude of 1 °C/60 sec. Data was analyzed using TA Universal Analysis 2000 software (TA Instruments, New Castle, DE).

### **3.3.6 Particle Size Analysis**

Particle size distribution, based on volume fraction, of the colloidal dispersions of Wet-milled ITZ and URF-ITZ was measured by static light scattering with a Malvern Mastersizer-S (Malvern Instruments, Ltd., Worcestershire, UK). The colloidal dispersion of URF-ITZ (equivalent to 20 mg ITZ/mL) was prepared by dispersing an aliquot of URF-ITZ powder (~ 170 mg) in 5 mL purified water by sonication on an ice bath. The colloidal dispersion of Wet-milled ITZ was prepared by dispersing an aliquot of Wet-milled ITZ powder (~ 100 mg) in 5 mL aqueous solution containing 1% mannitol and 0.4% lecithin to make the compositions same as the URF-ITZ dispersion. To measure the particle size distribution, the respective dispersion was then diluted with about 500 mL of

purified water to produce light obscuration in the range of 10–15%. Values reported are the average of at least three measurements.

### **3.3.7 Brunauer-Emmett-Teller (BET) Specific Surface Area Analysis**

Specific surface area was measured using a Nova 2000 version 6.11 instrument (Quantachrome Instruments, Boynton Beach, FL) with nitrogen as the adsorbate gas. An aliquot of powder was added to a 12-mm Quantachrome bulb sample cell and degassed for a minimum of 8 hr prior to analysis. Six points were taken over a range of relative pressures from 0.05 to 0.35. The data was then analyzed with the BET equation using NOVA Enhanced Data Reduction Software (version 2.13).

### **3.3.8 Dissolution Testing Under Supersaturated Conditions**

Dissolution testing at supersaturated conditions was conducted in a USP 25 dissolution apparatus model Vankel 7000 Dissolution Tester (Vankel Technology Group, Cary, NC) using 100 mL glass dissolution vessels and stirred with small paddles at 100 rpm. Simulated lung fluid containing 0.02% dipalmitoylphosphatidylcholine [40, 41] was used as the dissolution medium and pre-heated to 37 °C. Aliquots of the URF-ITZ and Wet-milled ITZ colloidal dispersions (equivalent of 80 µg ITZ, equal to 100-times of the equilibrium solubility ( $C_{eq}$ ) of crystalline ITZ) were added to the dissolution vessels (n = 6), respectively, within one second immediately after preparation. Aliquots of 2 mL of the dissolution media were taken at 5, 15, 30 min, 1, 2, 3, 6, 12 and 24 hr. The samples were immediately filtered through a 0.2 µm GHP Acrodisc filter (Pall Corporation, East Hills, NY), and diluted with acetonitrile for content analysis. The ITZ content was quantified using a Shimadzu LC-10A high performance liquid chromatography (HPLC)

system (Shimadzu Corporation, Columbia, MD) equipped with an Alltech Inertsil™ ODS-2 5  $\mu\text{m}$ , 150 mm  $\times$  4.6 mm, C-18 column (Alltech Associates, Inc., Deerfield, IL). The mobile phase was acetonitrile:water:diethanolamine (70:30:0.05) and it eluted the ITZ peak at approximately 5.5 min at 25 °C with a flow rate of 1 mL/min. The ITZ absorbance was measured at a wavelength  $\lambda_{\text{max}}$  of 263 nm. The supersaturation levels are reported as the drug concentration divided by the crystalline equilibrium solubility. Supersaturation was plotted versus time and area-under-the-supersaturation-curve (AUSC) was calculated by the linear trapezoidal rule.

### 3.3.9 *In Vitro* Aerosol Performance

An aliquot (5 mL) of the colloidal dispersions of the Wet-milled ITZ and URF-ITZ (equivalent to 20 mg/mL ITZ) were nebulized using an Aeroneb® Professional micropump vibrating mesh nebulizer (Nektar Inc., Mountain View, CA) for about 10 min. The *in vitro* deposition characteristics of the colloidal dispersions of Wet-milled ITZ and URF-ITZ for nebulization, was investigated using an eight-stage Andersen cascade impactor (Thermo-Electron Corp., Symrna, GA). The cascade impactor was assembled and operated in accordance with USP General Chapter 601 to assess the drug delivered. The flow rate of the nebulized aerosols was maintained by a vacuum pump (MFG Corp., Benton Harbor, MI) that was calibrated by a TSI mass flowmeter (Model 4000, TSI Inc., St. Paul, MN) to an air flow rate of 28.3 L/min. After deposition onto the stages of the impactor, the mass deposited on each of the impactor pieces was collected and the total mass of drug was quantified by HPLC. The aerosolization behavior was described in terms of total emitted dose (TED), mass median aerodynamic diameter (MMAD), geometric standard deviation (GSD), and percentage fine particle fraction (FPF; defined as the percentage of droplets with an aerodynamic diameter less than 4.7  $\mu\text{m}$ ). The

MMAD and GSD were obtained by plotting the cumulative mass found on the stages of the impactor as a function of the logarithm of the impactor stage cut-off diameter.

### **3.3.10 *In Vivo* Pulmonary Dosing of Rats**

With approval and in accordance with the Institutional Animal Care and Use Committee (IACUC) guidelines at The University of Texas at Austin, *in vivo* studies were conducted using jugular vein pre-catheterized CD<sup>®</sup> IGS Sprague-Dawley rats (Charles River Laboratories, Inc., Wilmington, MA), weighing 275 to 325 grams. Throughout the study the rats were housed individually, subjected to 12 h -12 h light and darkness cycles, with access to food and water *ad libitum*. The catheters were flushed daily with heparinized normal saline. After acclimatization for 3 days, eight rats in each formulation group were dosed by inhalation of the nebulized colloidal dispersions of the Wet-milled ITZ or URF-ITZ (equivalent to 20 mg/mL ITZ), respectively, for 10 min in a nose-only dosing apparatus, as shown in Figure 3.1. An Aeroneb<sup>®</sup> Professional micropump nebulizer was situated at the inlet of the dosing tube, and the nebulized drug aerosols went through the dosing tube with an air flow rate of 1 L/min. Following exposure to the aerosol cloud, serial blood samples (approximately 0.3 mL each) were withdrawn through the jugular vein catheter at 0, 0.5, 1, 1.5, 2, 2.5, 3, 4, 6, 8, 12 and 24 hr post dosing and placed into a pre-heparinized microcentrifuge tube. Equal volumes of saline were replaced after each sampling. Two rats in each dosing group were sacrificed immediately upon finishing inhalation to harvest the lungs for determining the lung deposition of the inhaled drug. The lungs of the other rats were harvested at 24 hr upon completing blood sampling.

### 3.3.11 Plasma and Lung Analysis

Plasma was separated by centrifugation at 3,000 g for 10 min in a 1.5 mL micro-centrifuge tube using a Microfuge<sup>®</sup> 18 centrifuge (Beckman Coulter, Fullerton, CA). The plasma and lung samples were stored at -80 °C until HPLC analysis. The lung homogenates were prepared by adding 1 mL of normal saline to a portion of about 0.5 g of the harvested lung and using a homogenizer (Omni International, Marietta, GA) in an ice bath. Drug levels of the calibration standards, plasma, and homogenized lung samples were analyzed using the following procedures. Briefly, to an aliquot of 250 µL plasma or 250 µL of lung homogenate, 50 µL of 0.3 N barium hydroxide, and 50 µL of 0.4 N zinc sulfate heptahydrate solutions were added and vortex mixed for 30 sec to precipitate water-soluble proteins. Acetonitrile (1 mL), containing 500 ng/mL ketoconazole as an internal reference standard, was added to each sample followed by vortex mixing for 1.5 min. Each sample was then centrifuged at 3,000 g for 15 min. The supernatant was transferred to a clean 1.5 mL micro-centrifuge tube and dried under a stream of nitrogen gas. Each sample was reconstituted with 250 µL mobile phase (62% acetonitrile: 38% 0.05 M potassium phosphate monobasic buffer adjusted to pH 6.7 with NaOH) and analyzed by HPLC with an Alltech Inertsil<sup>™</sup> ODS-2 5 µm, 250 × 4.6 mm, C-18 column protected by a C-18 guard column (5 µm, 7.5×4.6 mm) (Alltech Associates, Inc., Deerfield, IL). The injection volume was 100 µL, and the wavelength of absorption was 263 nm ( $\lambda_{\text{max}}$ ). The limit of detection and quantitation for ITZ was 10 ng/mL and 30 ng/mL, respectively. The column was maintained at 37 °C during the analysis. The ITZ peak eluted at approximately 18 min, and the ketoconazole peak eluted at 9.3 min at a mobile phase flow rate of 1.0 mL/min.

### **3.3.12 Pharmacokinetic and Statistical Analysis**

Plots of the log concentration of ITZ in plasma versus time exhibited a first-order absorption phase and a first-order elimination phase. A one-compartmental model for extravascular administration was therefore selected to assess the pharmacokinetic parameters of ITZ in rat plasma using WinNonlin Professional Version 2.1 (Pharsight Corporation, Mountain View, CA). All results are presented as mean $\pm$ SD. Student's *t* tests were conducted using SigmaPlot version 7 (Systat Software, Inc., Chicago, IL), to determine the significance between the two dosing groups. For all tests, statistical significance was defined by  $p < 0.05$ .

## **3.4 RESULTS AND DISCUSSION**

### **3.4.1 Physicochemical Properties of Wet-milled ITZ and URF-ITZ Formulations**

#### ***3.4.1.1 Morphology and Particle Size Distribution***

In the widely used wet milling process, comminution continually fractures drug crystals to reduce the particle size. The efficiency depends upon the nature of the grinding medium, the wetting of the solid, and the hardness of the drugs [42]. In the present study, because of the limited achievable rolling speed of the mill and hardness of ITZ, it took 10 days to reduce the particle size from an average size of 5  $\mu\text{m}$  (100% < 17.7  $\mu\text{m}$ ) to nano-size level. The low solubility of ITZ may be advantageous in suppressing crystal growth during and after the milling process, and the hardness (*i.e.* the high melting point) may favor comminution. From the SEM image in Figure 3.2(a), Wet-milled ITZ was composed of fractured, irregular shaped particles with various sizes, ranging from about 150 to 600 nm in length. This is consistent with a report that NanoCrystals of

beclomethsaone dipropionate can be prepared by ball milling a 5% w/w drug suspension in 2.5% PVA over a day, resulting in a mean size of 267 nm [42].

In contrast with Wet-milled ITZ, URF-ITZ powder exhibited a highly porous structure with more regularly round-shaped particles as shown in Figure 3.2(b). The SEM displayed aggregated nanoparticles that formed a porous matrix. Both the milling and URF process dramatically reduced ITZ particles to nano-size range compared to bulk micron-sized ITZ particles shown in Figure 3.2(c).

With the particle size reduction, the specific surface area of the Wet-milled ITZ and URF-ITZ powder were found to be 38.6 and 31.7 m<sup>2</sup>/g, respectively, which correspond to effective particle diameters of 150 and 190 nm (Table 3.1), assuming the particles were monodisperse and in spherical shape. The surface area of the bulk particles of 2.20 m<sup>2</sup>/g was 15 times smaller.

However, the particle size distribution analysis using static laser light scattering showed D(v, 0.5) and D(v, 0.9) (diameter at which the cumulative sample volume was under 50% and 90%, respectively) values of 0.57 and 1.22 μm, respectively, for Wet-milled ITZ in colloidal dispersion (Table 3.1). This value is larger than that inferred from the measured surface area and SEM. Though the primary particle size of Wet-milled ITZ is ~190 nm from the surface area, the potential for increased Van der Waals interactions and electrostatic attraction between ultrafine particles can lead to aggregates ranging from loose flocculates to completely fused particles [13]. It is possible that some of the primary particles formed aggregates that were detected by static light scattering. Nevertheless, over 80% of the particles had a diameter of 1 micron or less.

In comparison, the URF-ITZ colloidal dispersion showed a narrow and smaller range with  $D(v, 0.5)$  and  $D(v, 0.9)$  of 0.25 and 0.59  $\mu\text{m}$ , respectively. The stable and relatively uniform particle sizes resulted from the rapid nucleation during ice formation in URF and arrested growth as the solution freezes as discussed previously [34].

#### ***3.4.1.2 Crystalline State Evaluation***

From the XRD diffraction profiles in Figure 3.3, ITZ exhibited intense characteristic crystalline peaks at 14.35, 17.46, 20.31, and 23.41 2-theta degrees, as seen in the micron-sized bulk ITZ (as purchased from the manufacturer). The XRD patterns of Wet-milled ITZ were found to be superimposable to the spectra of the micronized crystalline ITZ but with smaller peak heights. Reducing particle size can result in XRD peak broadening and halo formation, due to lost long-range crystalline order, without complete transition to an amorphous form [43]. It was also reported that XRD profiles of asulacrine nanocrystals with a mean particle size of 130 nm made by high pressure homogenization were not affected, with similar peak intensities as for micron-sized drug [22]. The XRD patterns of nanocrystal therefore seem material-specific and are related to the crystalline microstructure (crystal size, micro-strain and defects) of individual substances [43]. Therefore, the reduction in XRD peak intensity of Wet-milled ITZ is most likely due to particle size reduction.

For XRD of URF-ITZ powder in Figure 3.3, broad, diffuse haloes were present with an absence of the characteristic crystalline peaks, indicating a highly amorphous morphology [29]. The crystallinity was examined further with MTDSC as shown in Figure 3.4. The URF-ITZ powder exhibited a glass transition at around 50 °C, one

exothermic recrystallization peak, and finally a single endothermic melting peak at 165.7 °C. These results further confirmed the amorphous nature of URF-ITZ seen by XRD. In contrast, an exothermic peak was not present for Wet-milled ITZ, but only a single endothermic peak at 163.4 °C, corresponding to the melting of ITZ. However, the melting peak of Wet-milled ITZ was not as sharp as for bulk ITZ and shifted slightly.

Milling processes may generate amorphous domains on the particle surface [44]. Despite the long time period for milling the ITZ, the crystallinity was high and the amorphous content undetectable according to the XRD and DSC results.

#### **3.4.2 Supersaturation of Wet-milled ITZ and URF-ITZ Colloidal Dispersions in Simulated Lung Fluid**

Dissolution of the ITZ colloidal dispersions in simulated lung fluid with pH 7.4 at 37 °C was conducted under supersaturated conditions (100-times  $C_{eq}$  equivalent ITZ were added) as shown in Figure 3.5. The  $C_{eq}$  in simulated lung fluid was measured to be 10 ng/mL after shaking at 37 °C for 3 days with excess crystalline ITZ present. For the URF-ITZ,  $C/C_{eq}$  reached 22-times at 5 min and a maximum value of about 26-times at 15 and 30 min. The supersaturation levels gradually decreased to about 7-times at 2 hr, and 5-times at 24 hr. In contrast, the supersaturation for Wet-milled ITZ only reached about 3-times the measured  $C/C_{eq}$  at 30 min, fell to about 2-times at 6 hr and then gradually declined to about unity, the equilibrium ratio at 24 hr. The cumulative extent of supersaturation was calculated as the AUSC, which was 1785 and 383 ng·hr/mL for URF-ITZ and Wet-milled ITZ, respectively. The much larger  $C_{sat}$  at various times and AUSC for the amorphous URF-ITZ have the potential to enhance bioavailability of this poorly water soluble drug.

Formation of a high energy amorphous or semicrystalline state can increase the predicted solubility, in many cases up to 100 times that of its crystalline form [26, 31]. The URF-ITZ formulation has been previously identified to be a solid solution of ITZ molecularly dispersed in mannitol and lecithin matrix [34]. Once the solid solution was exposed to the aqueous simulated lung fluid, the excipients dissolved very rapidly and the high surface area ITZ domains quickly supersaturated the dissolution medium. Because of the maximal achievable surface area for dissolution obtained by solid solution [45], the dissolution rate and  $C_{sat}$  value of URF-ITZ colloidal dispersion could be much higher than the nanocrystalline ITZ colloidal dispersion upon added to a dissolution medium. The elevated  $C_{sat}$  value of URF-ITZ might therefore be responsible for the 4.7-times higher amount of solvated ITZ molecules in the simulated lung fluid than Wet-milled ITZ.

The driving force for dissolution depends on the drug solubility within a given environment (*i.e.* lung fluid)  $C_{sat}$  and the concentration gradient between  $C_{sat}$  at the particle surface and  $C$  in the bulk solution phase. Particle dissolution is governed by several factors that can be described by the Noyes-Whitney equation:

$$dM/dt = AD(C_{sat}-C)/h$$

where  $dM/dt$  is the fraction of mass dissolved per unit time,  $A$  is the surface area available for dissolution,  $D$  is the diffusion coefficient, and  $h$  is the thickness of the diffusion boundary layer. Nanoparticles often dissolve more quickly due to the extensive enhancement in surface area, the smaller  $h$  which is proportional to the particle diameter and the higher  $C_{sat}$  because of particle curvature according to the Kelvin equation [46-48]. The nano-sized URF-ITZ and Wet-milled ITZ both dissolved rapidly and reached a

maximum concentration within 30 min, as well as supersaturation relative to equilibrium solubility of the micronized ITZ. The  $D$  value was the same for both formulations, and the available surface areas  $A$  were similar. Also the  $h$  values which are closely related to particle size [49] were similar. Thus the higher dissolution rate for the amorphous ITZ is due to the higher  $C_{sat}$  values.

### **3.4.3 *In Vitro* Aerosol Performance of Wet-milled ITZ and URF-ITZ Aqueous Colloidal Dispersions**

Pulmonary drug delivery targeted to the alveoli is advantageous and critical for systemic absorption [50], as the distance from the air in the alveolar lumen to the capillary blood flow is less than 400 nm [51]. The efficacy of pulmonary delivery of drug to the deep lung is largely determined by the particle size distribution of aerosol droplets [52]. The inhaled aerosol should possess a narrow range of aerodynamic diameters between 1-5 micron to pass through the filter of the mouth and throat to be effectively delivered inside the lung [25]. The aerodynamic particle size of the nebulized colloidal dispersions of Wet-milled ITZ and URF-ITZ for inhalation, with an equivalent of 100 mg ITZ in 5 mL, is summarized in Table 3.2. The TED of Wet-milled ITZ and URF-ITZ were 51.73 and 56.40 mg out of 100 mg ITZ available for nebulization, respectively. Their corresponding FPF were 47.28 and 54.39% with the respective fine particle dose (defined as the amount of aerosol droplets entering the impactor less than 4.7  $\mu\text{m}$ ,  $\text{TED} \times \text{FPF}$ , indication of the dose delivered to the deep lung) delivered at a rate of 2.45 and 3.07 mg/min. The MMAD of the atomized droplets of Wet-milled ITZ and URF-ITZ colloidal dispersions were 2.78 and 2.36  $\mu\text{m}$  with GSD of 3.06 and 2.66, respectively, which are suitable for deep lung delivery.

In this study, the aerodynamic diameter is governed by the easily controllable nebulization of the aqueous droplets, which contain much smaller dispersed particles of drug. It was reported that the Aeroneb<sup>®</sup> Professional micropump nebulizer produced an aqueous mist of fine droplets with sizes ranging between 1 and 4  $\mu\text{m}$  [36]. Nanoparticles with a diameter of less than 1  $\mu\text{m}$  are more easily incorporated in the respirable aerosolized droplets with MMAD of 1–5  $\mu\text{m}$  [53, 54]. Furthermore, the viscosities of the colloidal dispersions are similar to those of the water. The low viscosity facilitates the formation of small and uniform droplets [55]. Since both URF-ITZ and Wet-milled ITZ colloidal dispersions contain submicron particles, the aerodynamic performance of the nebulized fine aerosol droplets is similar to that of pure water.

#### **3.4.4 Pharmacokinetics of Inhaled Wet-milled ITZ and URF-ITZ in Rats**

With the same compositions and comparable *in vitro* aerodynamic performance of the nebulized aerosols of Wet-milled ITZ and URF-ITZ colloidal dispersions, their *in vivo* performance was subsequently explored in a rat model. Rats were exposed nose-only to a single dose aerosols of the nebulized colloidal dispersions (equivalent to 100 mg of ITZ total), respectively, for about 10 min. Drug concentration profiles in lung tissue and blood following a single inhalation dose are presented in Figures 3.6 and 3.7. Upon completing inhalation of the nebulized compositions (0 hr post dosing),  $12.28 \pm 0.60$  and  $11.01 \pm 4.26$   $\mu\text{g/g}$  wet lung weight of ITZ were found deposited in lungs from Wet-milled ITZ and URF-ITZ dosing groups, respectively. At 24 hr post dosing, these values were  $562 \pm 443$  and  $455 \pm 237$  ng/g wet lung weight, respectively.

Once deposited in the lungs, the nanoparticles underwent dissolution in the lung lining fluid to release free ITZ molecules for lung local action or were further absorbed

through lung alveolar epithelium to systemic circulation. The corresponding pharmacokinetic parameters in blood are summarized in Table 3.3. In plasma, based on a one compartmental analysis, the  $C_{\max}$  for Wet-milled ITZ and URF-ITZ dosing group were 50.4 and 177.5 ng/mL at 2.7 and 4.0 hr after dosing, respectively. The  $AUC_{0-24}$  of Wet-milled ITZ and URF-ITZ were 662 and 2543 ng·hr/mL, respectively. In URF-ITZ dosing group, after reaching the  $C_{\max}$ , a plateau of the high ITZ level was maintained from 2.5 to 6 hr, similar to a sustained release profile. At all the sampling time points, the ITZ levels in rats inhaled URF-ITZ were significantly higher than those inhaled Wet-milled ITZ.

Despite the comparable lung deposition levels of the inhaled aerosols of the two ITZ colloidal dispersions, the cumulative ITZ concentrations absorbed into blood from rats was about 3.8-times higher for the URF-ITZ versus Wet-milled ITZ. From Fick's first law, the systemic absorption rate of a drug from the lung epithelium is given by  $P \times A \times C$ , where  $P$  is membrane permeability,  $A$  is the available surface area over which the drug is spread,  $C$  is the drug concentration in the lung lining fluids. The drug concentration in blood is assumed to be insignificant compared to the lung concentration and the transfer from lung to blood is irreversible [56]. For the Wet-milled ITZ and URF-ITZ colloidal dispersions, many factors were fairly constant include the composition, aerodynamic performance, lung depositions, total drug dose, permeability and absorption area. The absorption has been shown to be permeation limited for both amorphous and crystalline ITZ nanoparticles of the sizes on the order of 200-600 nm with a combined dissolution/permeation material balance in the lung fluid [34]. Here the dissolution is essentially instantaneous relative to the permeation. In this case, the flux of ITZ into systemic circulation would be directly proportional to the dissolved concentration  $C_{sat}$ .

This prediction was observed in the current study. The 3.8-times larger AUC of URF-ITZ in the systemic circulation versus Wet-milled ITZ was on the same order as the 4.7-times larger supersaturation level (thermodynamic activity) measured in the *in vitro* dissolution test.

The biopharmaceutical consequences of solubility differences of polymorphs are directly related to the solubility difference [57]. It was reported that polymorphs of chloramphenicol palmitate with a measured solubility ratio of about 4.0 induced about 6-times difference in  $C_{\max}$  in human after oral administration [58]; whereas no significant difference in pharmacokinetics was observed after a single oral dose of polymorphs of mefenamic acid with measured solubility ratio of about 1.3 [57]. Therefore, to achieve clinically meaningful biopharmaceutical consequences of solubility differences, the solubility ratios need to be about two fold higher [26]. Compared to the crystalline counterpart, the formation of significantly higher levels of supersaturation offered by amorphous formulations of drugs with poor/erratic bioavailability, enhances total drug absorption (AUC) and  $C_{\max}$  while reducing  $t_{\max}$  as observed for oral [59, 60], topical [61] and pulmonary [62] administrations. The use of amorphous form of poorly water-soluble drugs has widened the window of achievable pharmacokinetic performance enormously.

#### **3.4.5 Lung Clearance of the Deposited Nanoparticles Containing ITZ**

In addition to influencing aerosol deposition and dissolution in the lung lining fluid, particle size distribution and morphology also may influence the clearance mechanism [44, 63]. The lungs have very efficient clearance mechanisms for foreign particles. The MMAD of Wet-milled ITZ and URF-ITZ aerosols favor deposition in the deep lung, bypassing the mucociliary clearance in the airways. Compared to Wet-milled

ITZ, the deposited amorphous URF-ITZ nanoparticles dissolve more quickly upon exposure to the lung lining fluid. Furthermore the rapid dissolution may minimize crystallization of undissolved particles of URF-ITZ in the lung fluid, which would otherwise lower the supersaturation [64, 65]. The more rapid dissolution and resulting higher supersaturation with minimal time for crystallization of undissolved solid results in reduced clearance of URF-ITZ relative to Wet-milled ITZ particles by the lung defense system. These factors favor the observed significantly enhanced bioavailability of URF-ITZ.

For those deposited particles have not completely dissolved, they would mainly be cleared from the alveoli via endocytosis by epithelial and endothelial cells, and phagocytosis by macrophages [66, 67]. The efficiency of clearance of the inhaled particles is size-dependent. Alveolar macrophages preferentially uptake particles of approximately 1 to 3  $\mu\text{m}$  in diameter [25, 68]. Phagocytosis of 1  $\mu\text{m}$  particles has been observed as early as 15 min after nebulization [69]. Furthermore, 30–60% of 1–3  $\mu\text{m}$  particles have been observed to be phagocytosed 2–4 h post intra-tracheal instillation, with complete pulmonary clearance of particles within 24 h [70]. After 24 hr post inhalation the ITZ levels in the lung were similar for the URF-ITZ and Wet-milled ITZ, even though the former was absorbed at a level of  $\sim 4$  times higher. Thus the much larger amount of unabsorbed Wet-milled ITZ particles must have been cleared by the lung defense system. The aggregates of the Wet-milled ITZ of 590 nm in mean diameter measured by light scattering are more vulnerable to uptake by macrophage clearance than the smaller URF-ITZ particles, so that ITZ levels in lung at 24 hr post inhalation were both significantly reduced.

### 3.5 CONCLUSION

For an aqueous colloidal dispersion of amorphous nanoparticulate ITZ, rapid dissolution produced a supersaturation  $\sim 4.7$ -times larger than for a dispersion of crystalline nanoparticulates made by wet milling with the same composition and similar particle surface area. The aerodynamic diameters for both dispersions were suitable for deep lung delivery by nebulization, and similar to values produced for pure water. However, the increase in the systemic bioavailability for the amorphous versus crystalline dispersion of about 3.8 was approximately the same as the increase in supersaturation measured *in vitro* in the simulated lung fluid. The experimentally observed similarity in the values of bioavailability and supersaturation would be predicted for a permeability controlled model, where dissolution is very rapid, as suggested previously [34]. The high supersaturation, favored by rapid dissolution of amorphous nanoparticles, prior to particle clearance or crystallization favors the high permeability into the bloodstream. Pulmonary delivery of amorphous nanoparticle formulations of extremely poorly water-soluble drugs, especially for high-dose drugs (e.g. ITZ), is thus beneficial for both local and systemic therapy.

## **Chapter 4: In Vitro Characterization and Pharmacokinetics in Mice following Pulmonary Delivery of Itraconazole as a Cyclodextrin Solubilized Solution**

### **4.1 ABSTRACT**

This study aims to make a 2-hydroxypropyl- $\beta$ -cyclodextrin (HP $\beta$ CD) solubilized itraconazole (ITZ) solution (i.e., HP $\beta$ CD-ITZ) suitable for pulmonary delivery by nebulization, and compare the pharmacokinetics of inhaled nebulized aerosols of HP $\beta$ CD-ITZ versus a colloidal dispersion of an ITZ nanoparticulate formulation (i.e., URF-ITZ). Solid state characterizations of lyophilized HP $\beta$ CD-ITZ by differential scanning calorimetry (DSC), Fourier Transform Infrared Spectroscopy (FTIR), and X-ray photoelectron spectroscopy (XPS) indicated the formation of dynamic inclusion complexes between ITZ and HP $\beta$ CD. Nebulized aerosols of both HP $\beta$ CD-ITZ and a colloidal dispersion of URF-ITZ were confirmed suitable for deep lung delivery. Single doses of the nebulized aerosols (equivalent to 5.3 mg ITZ/mL in 5 mL) in mice produced similar ITZ lung depositions and pharmacokinetic profiles, with ITZ lung levels of approximately 4  $\mu$ g/g wet lung weight upon completion of nebulization and remained above 0.5  $\mu$ g/g at 24 hr. HP $\beta$ CD-ITZ demonstrated faster systemic absorption of ITZ across lung epithelium than URF-ITZ, with  $T_{\max}$  values of 1.5 and 3.0 hr, and  $AUC_{0-\infty}$  of 2513 and 3717 ng·hr/mL, respectively. The fast absorption of solubilized ITZ across lung mucosal surface may be due in part to the elimination of the phase-to-phase transition.

## 4.2 INTRODUCTION

The incidence of invasive fungal infections has continued to increase over the last decade especially among high risk patients including those undergoing chemotherapy, solid organ or hematopoietic stem cell transplantation, and patients in intensive care units [1, 2]. The azole antifungals, which inhibit lanosterol 14- $\alpha$ -demethylase resulting in reductions in ergosterol within the fungal cell membrane, are a mainstay in the treatment of invasive fungal infections. Itraconazole (ITZ) is an appealing antifungal triazole for both prophylaxis and treatment in neutropenic and other immunocompromised patients, because of its broad spectrum of activity and enhanced potency against commonly occurring fungal pathogens including *Candida* and *Aspergillus* species [3].

ITZ has a well-defined correlation between its *in vitro* minimal inhibitory concentration (MIC) activity and clinical performance in the treatment of candidiasis [4]. For susceptible organisms (MIC < 0.125  $\mu\text{g/ml}$ ), 89% of patients are cured clinically when ITZ plasma concentration is greater than 0.5  $\mu\text{g/mL}$ . For *Aspergillus* sp. infections in immunocompromised patients, ITZ trough levels greater than 0.5  $\mu\text{g/g}$  in lung tissue, or greater than 0.5  $\mu\text{g/mL}$  in blood [5] are generally required. However, being classified as a Biopharmaceutical Classification System (BCS) class II compound, ITZ is practically insoluble in water (estimated aqueous solubility is approximately 1 ng/mL at neutral pH and 6  $\mu\text{g/mL}$  at pH 1) [6]. The low solubility presents significant challenges in formulating sufficiently bioavailable dosage forms of ITZ, irrespective of routes of administration. A number of formulation approaches have been assessed in order to improve the pharmaceutical performance of ITZ [7], such as solubilization in surfactants to form self-emulsifying drug delivery systems [8, 9], solid state manipulation using particle engineering technologies [10-12], and formation of drug/cyclodextrin (CD)

inclusion complexes. Among these formulation approaches, the first to be commercialized was Sporanox<sup>®</sup> oral capsules, in which ITZ is molecularly dispersed with hydroxypropylmethylcellulose forming a solid solution [6]. However, the oral bioavailability is low, with erratic absorption influenced by food intake [13]. An alternative oral solution (Sporanox<sup>®</sup>, ITZ/HP $\beta$ CD inclusion complex containing 10 mg/mL of ITZ and 400 mg/mL of HP $\beta$ CD) further increased bioavailability to about 30% higher than the capsule formulation [14]. However, the significant gastrointestinal adverse effects caused by HP $\beta$ CD, including osmotic diarrhea [15], led to limited patient acceptance. Newer formulations and/or delivery systems of ITZ with greater therapeutic efficacy and lower toxicity are still in demand.

The lungs are often the primary port of entry into the body and site of infection for many life-threatening opportunistic fungi in immuno-compromised patients [16]. However, pulmonary infections may not respond well to systemic therapy with oral dosage forms due to insufficient drug diffusion into pulmonary tissues and lumen [17]. An increase in the amount of drug doses intended to compensate for poor diffusion may lead to systemic toxicity. Delivering antifungal drugs as aerosols by the pulmonary route allows high drug concentrations targeted directly at the site of infection, while minimizing potential systemic toxicity.

Production of drug-loaded nanoparticles such as nanosuspensions for the poorly-water soluble drugs is an alternative and promising approach to overcome their low aqueous solubilities and the consequential low bioavailabilities [18]. Moreover, drug-loaded nanoparticles have the potential to be used for pulmonary delivery of therapeutics for treating lung diseases locally as well as for systemic actions. Pulmonary delivery of

nanoparticle formulations of poorly water-soluble drugs showed promising results in several *in vitro* investigations [19, 20], *in vivo* studies [21], and in a clinical trial of a nebulized nanocrystal suspension of budesonide (75–300 nm) [22].

Nanoparticle formulations of ITZ for deep lung delivery have been designed and prepared by particle engineering technologies in our laboratory, namely evaporative precipitation of aqueous solution (EPAS) [23] and spray freezing into liquid (SFL) [24]. Single and multi dose inhalation of nebulized aerosols of these ITZ nanoparticle colloidal dispersions with a suitable aerodynamic diameter for deep lung delivery, demonstrated therapeutically effective ITZ concentrations in mouse lung, superior to the Sporanox<sup>®</sup> oral solution [25, 26]. In addition, the inhaled ITZ formulations demonstrated prophylactic effects against invasive pulmonary aspergillosis in murine models [27, 28].

A novel nanostructured ITZ solid solution formulation, URF-ITZ (ITZ:mannitol:lecithin=1:0.5:0.2, weight ratio) was recently developed using the ultra-rapid freezing (URF) technology [29]. Inhalation of nebulized URF-ITZ aqueous colloidal dispersion, containing the same amount ITZ loading as the previously reported ITZ pulmonary formulations on the same murine model [25], produced significantly enhanced lung drug deposition and more than 10-fold higher ITZ level in the systemic circulation. The improved bioavailability was mainly attributed to the smaller nano-scaled particle size (primary particles of 30-50 nm in diameter), and the presence of lecithin, which had facilitated permeation of ITZ through the lung epithelium [30].

CDs have been reported to facilitate faster systemic absorption and improved bioavailability of poorly water-soluble drugs after pulmonary administration of aerosols

or solutions as compared to equipotent alternative formulations or routes of administration [31, 32]. A recent study reported that pulmonary delivery of a nebulized Vfend<sup>®</sup> I.V. aqueous solution of voriconazole (a triazole analog of ITZ) solubilized with sulfobutylether- $\beta$ -cyclodextrin (SBE $\beta$ CD) to rodents, attained a high lung deposition and a high systemic peak drug level within 30 min, similar to the intravenous administration profile [33]. The presence of the solubilized form of voriconazole molecules in a SBE $\beta$ CD aqueous solution was thought to contribute to the rapid and complete absorption, and high systemic drug concentrations following pulmonary administration.

Based on the results of the bioavailability studies of inhaled nanoparticulate ITZ and CD-solubilized voriconazole formulations, we hypothesized that inhalation of an effectively solubilized form of poorly-water soluble drug could lead to faster absorption through the lung mucosal epithelium as compared to the nanoparticulate form, which requires a drug dissolution process prior to absorption. Our aims were two-fold: (1) to prepare and characterize a CD solubilized ITZ solution formulation suitable for pulmonary delivery by nebulization; (2) to investigate the pharmacokinetic profiles of the inhaled aerosol of the CD solubilized form of ITZ compared to a nanoparticulate colloidal dispersion of this triazole in mice following nebulization in a whole-body exposure dosing apparatus.

## **4.3 MATERIALS AND METHODS**

### **4.3.1 Materials**

Crystalline ITZ (micronized pharmacopeial grade) was purchased from Hawkins Chemical (Minneapolis, MN, USA). Hydroxyitraconazole was purchased from BDG

Synthesis (Wellington, New Zealand). Mannitol and lecithin (NF grade) were from Spectrum Chemicals (Gardena, CA). 2-hydroxypropyl- $\beta$ -cyclodextrin (HP $\beta$ CD) was kindly provided by Roquette America Inc. (Keokuk, IA). 1,4-dioxane, acetonitrile, and diethanolamine were purchased from Fischer Chemicals (Gibbstown, NJ, USA). All organic solvents used were of HPLC grade. Other chemicals utilized in this study were at least of ACS grade. Blank mice serum for chromatography analysis method validation was supplied by Invitrogen (Camarillo, CA, USA).

#### **4.3.2 Preparation of Nanostructured Aggregates Powder of ITZ Using URF Technology**

The amorphous nanostructured aggregate powder URF-ITZ, was prepared using URF technology as described previously [29]. In brief, ITZ, mannitol, and lecithin (in a weight ratio of 1:0.5:0.2) were dissolved in a mixture of 1,4-dioxane and purified water (65/35, v/v) co-solvent system. The solution was then applied to the cryogenic solid substrate (which was previously cooled to -70 °C) of the URF apparatus. The rapidly frozen solids were collected and lyophilized using a VirTis Advantage bench top tray lyophilizer (The VirTis Company, Inc., Gardiner, NY, USA). The resultant dry powder was stored in a desiccator under vacuum at room temperature. Amorphous pure ITZ was also prepared by the URF process as described above.

#### **4.3.3 Characterization of HP $\beta$ CD and HP $\beta$ CD-ITZ Solutions**

A series of concentrations of HP $\beta$ CD solutions in purified water were prepared. Viscosity of the solutions was measured using a Cannon-Fenske Routine viscometer (Cannon Instrument Company, State College, PA, USA) at 25 °C.

Considering the osmolality of the formulation to be delivered to the lungs, a sodium chloride (NaCl) solution in water with the proper osmolality, was used to prepare the HP $\beta$ CD solutions. The osmolality of the HP $\beta$ CD-ITZ solution was measured by the freezing point depression method using a  $\mu$ Osmette Micro Osmometer (Precision Systems Inc., Natick, MA).

The pH of the filtrates of the dispersions of ITZ in HP $\beta$ CD was determined using an Orion 350 PerpHecT® Advanced Benchtop pH Meter (Thermo Fisher Scientific, Waltham, MA).

#### **4.3.4 Solubility Studies**

To study solubility differences between crystalline and amorphous ITZ in HP $\beta$ CD, excess amounts of micronized crystalline ITZ or amorphous pure ITZ were added to 5 mL of 15% HP $\beta$ CD in purified water. A 2-min sonication by a probe sonicator (Branson Sonifier 450, Danbury, CT) was used to facilitate the dispersion of the powders into the aqueous phase. The formed dispersions were then shaken at 100 rpm, at 25 °C for up to 2 days. Aliquots of 200  $\mu$ L of the suspension were withdrawn at 0, 0.5, 1, 2, 3, 5, 8, 24, 48 hr. All samples were filtered through 0.2  $\mu$ m GHP Acrodisc syringe filters (Pall Corporation, East Hills, NY) and appropriately diluted with a solvent mixture of acetonitrile:water (70:30, v/v) for content analysis. The ITZ content was determined using a Shimadzu LC-10A high performance liquid chromatography (HPLC) system (Shimadzu Corporation, Columbia, MD) equipped with an Alltech Inertsil™ ODS-2 5  $\mu$ m, 150 mm  $\times$  4.6 mm, C-18 column (Alltech Associates, Inc., Deerfield, IL). The ITZ peak was eluted at approximately 5.5 min using a mobile phase consisting of acetonitrile:water:diethanolamine (70:30:0.05, v/v/v) at a flow rate of 1 mL/min, column

temperature of 25 °C, and an absorption wavelength  $\lambda_{\text{max}}$  of 263 nm. Values reported are the average of three measurements.

#### **4.3.5 Preparation of Solid State ITZ-HP $\beta$ CD Inclusion Complex**

Aliquots of the ITZ in 15% HP $\beta$ CD dispersion were sampled at 24 hr after dispersion and equilibration at room temperature, and filtered through 0.2  $\mu\text{m}$  Acrodisc filters (Pall Corporation, East Hills, NY). The filtrates (designated as HP $\beta$ CD-ITZ solution) were frozen and then lyophilized using the VirTis Advantage bench top tray lyophilizer (The VirTis Company, Inc., Gardiner, NY, USA) to obtain dry powders.

#### **4.3.6 Preparation of Physical Mixture**

A physical mixture consisting of micronized crystalline ITZ and HP $\beta$ CD powder was prepared by gently mixing ITZ and HP $\beta$ CD powders for 5 min using a spatula in a glass mortar to obtain a homogeneous blend at the same weight ratio as the lyophilized HP $\beta$ CD-ITZ inclusion complex, based on the equilibrium solubility of ITZ per mL of 15% HP $\beta$ CD solution.

#### **4.3.7 Thermal Analysis**

All the powders were dried in desiccator for at least one day before thermal analysis. Differential scanning calorimetry (DSC) of the lyophilized HP $\beta$ CD-ITZ dry powder, physical mixture, and each pure component was conducted using modulated temperature DSC (MTDSC), Model 2920 (TA Instruments, New Castle, DE), equipped with a refrigerated cooling system. Dry nitrogen gas was used as the purge gas through the DSC cell at a flow rate of 40 mL/min. Samples weighing 10-15 mg in crimped

aluminum pans (Kit 0219-0041, Perkin-Elmer Instruments, Norwalk, CT) were used. The mass of the empty sample pan was matched with that of the empty reference pan within  $\pm 0.2$  mg. Samples were heated at a ramp rate of 10 °C/min from 0 to 250 °C with a modulation temperature amplitude of 1 °C /60 sec for all studies. Data was analyzed using the TA Universal Analysis 2000 software (TA Instruments, New Castle, DE).

#### **4.3.8 Fourier Transform Infrared Spectroscopy (FTIR)**

ITZ, HP $\beta$ CD, physical mixture powders, and the lyophilized HP $\beta$ CD-ITZ dry powder were analyzed by FTIR to evaluate potential interactions. The samples were prepared by weighing approximately 4 mg of the material for analysis, homogenously dispersing in dried KBr of about 300 mg using a mortar and pestle, and compressing the powder under vacuum with a compression force of 10 tons using a 13 mm diameter round flat face punch for three minutes to produce a pellet compacts. The sample was placed in the IR light path and the IR spectra were recorded using a Thermo Mattson Infinity Gold FTIR with Spectra-Tech Thermal ARK module from 400 to 4000  $\text{cm}^{-1}$  in transmission mode equipped with a KBr beamsplitter and DTGS detector having a resolution of 1  $\text{cm}^{-1}$ .

#### **4.3.9 X-ray Photoelectron Spectroscopy (XPS)**

XPS analysis was performed on the lyophilized powder comprised of HP $\beta$ CD/ITZ inclusion complexes sampled at 1, 24 and 48 hr after dispersion, as well as physical mixture in order to verify the amount of ITZ present on the powder surfaces. The XPS measurements were conducted with an AXIS HS photoelectron spectrometer (Kratos Analytical, UK) equipped with a monochromated Al K $\alpha$  x-ray source ( $h\nu =$

1486.6 eV) operating at 10 kV and 15 mA (150 W). The vacuum in the sample chamber was maintained below  $10^{-7}$  torr during analysis. The analysis area was approximately 1 mm<sup>2</sup>. For each sample, a take-off angle of the photoelectrons perpendicular to the sample holder was used throughout. The data for the atomic surface composition were converted into molecular surface composition under the assumptions that all molecular species on the surface are present in “patches” with a depth of at least the depth of analysis (~5 nm for the powders), and the surface can be regarded as linear combination of the different molecular species.

#### **4.3.10 Aerosol Particle Size Analysis Using a Cascade Impactor**

The colloidal dispersion of URF-ITZ powder was prepared for nebulization by dispersing the powder in purified water using ultrasonication in an ice bath. An aliquot (5 mL) of the URF-ITZ colloidal dispersion and HP $\beta$ CD-ITZ aqueous solution were nebulized using an Aeroneb<sup>®</sup> Professional micropump nebulizer (Nektar Therapeutics, San Carlos, CA) with an air flow rate of 28.3 L/min. The characterization of aerodynamic droplet size distribution was conducted according to the guidelines in USP 30 Section 601 [34].

Aerodynamic droplet size distributions were determined using a USP Apparatus 1 non-viable eight-stage cascade impactor (Thermo-Anderson, Symrna, GA) with a spacer to quantify total emitted dose (TED) from the nebulizer output, mass median aerodynamic diameter (MMAD), geometric standard deviation (GSD), and percentage fine particle fraction (FPF; defined as the percentage of droplets with an aerodynamic diameter less than 4.7  $\mu$ m). Fiberglass filters (81 mm diameter) (ThermoFisher Scientific, Franklin, MA) were set atop each impactor plate to absorb the aerosolized suspensions

and prevent overload of the plates. Each stage was rinsed with a known volume of the washing solution (acetonitrile/water=70/30, v/v). Each filter was placed in a separate container with a known volume of the washing solution and sonicated for 30 min to dissolve ITZ. Samples were filtered using 0.2 µm GHP Acrodisc syringe filters prior to quantification of drug contents using HPLC.

#### **4.3.11 Single-dose Pulmonary Administration to Mice**

Male outbred ICR (Institute for Cancer Research) mice (Harlan Sprague Dawley, Inc., Indianapolis, IN) weighing 25–28 g were acclimated in a whole-body dosing chamber as previously described [26] for 20 min/day for 2 days prior to dosing. This restraint-free chamber was designed to hold up to 14 mice. An Aeroneb<sup>®</sup> Professional micropump nebulizer was fitted at the inlet of the chamber, and the aerosols were delivered through the inlet into the chamber with an air flow rate of 1 L/min. Nebulized aerosols of HPβCD-ITZ solution and URF-ITZ colloidal dispersion were inhaled by the mice for approximately 18 min in the whole-body dosing chamber. Following exposure to the aerosol cloud, six mice were euthanized by carbon dioxide narcosis at 0, 0.5, 1, 1.5, 2, 3, 4, 6, 10, and 24 hr post dosing. Samples taken immediately upon completion of aerosolization were assigned to the zero time point. Blood samples were taken by cardiac puncture, and the lungs were collected following exsanguination. The study protocol was approved and conducted in accordance to the Institutional Animal Care and Use Committee (IACUC) guidelines at The University of Texas at Austin. Throughout the study the animals were maintained in accordance with the American Association for Accreditation of Laboratory Animal Care guidelines.

#### 4.3.12 Chromatographic Analysis

Whole blood samples were centrifuged at 3000 g for 15 min to obtain the serum. Serum samples and whole lungs were stored at -80°C until assayed. Lungs were thawed and homogenized with 1 mL of purified water using an Omni Ruptor 250 ultrasonication homogenizer (Omni International, Marietta, GA) with power output setting at 40 and pulser at 60.

Calibration standards, serum, and homogenized lung samples were analyzed as described previously [29]. Briefly, serum samples of 250  $\mu$ L were transferred to clean 2-mL microcentrifuge tubes. To each microcentrifuge tube, 50  $\mu$ L of 0.3 N barium hydroxide and 50  $\mu$ L 0.4 N zinc sulfate heptahydrate solutions were added and vortex mixed for 30 sec to precipitate water-soluble proteins. Acetonitrile (1 mL) containing about 500 ng/mL voriconazole as an internal standard was added to each sample followed by vortex mixing for 1.5 min. Samples were then centrifuged at 3000 g for 15 min. The supernatant from each vial was transferred to a clean 1.5 mL centrifuge tube and dried in an aluminum heating block (70 °C) under a stream of nitrogen gas. The samples were reconstituted with 250  $\mu$ L mobile phase (0.05 M phosphate buffer, pH 6.7: acetonitrile = 38:62, v/v), vortex mixed for 1 min, and centrifuged at 6000 g for 5 min. An aliquot of 150  $\mu$ L was pipetted into HPLC vial spring inserts and analyzed using Shimadzu HPLC system with an Alltech Inertsil<sup>TM</sup> ODS-2 5  $\mu$ m, 250  $\times$  4.6 mm, C-18 column connected to a C-18 guard column (5  $\mu$ m, 7.5 $\times$ 4.6 mm) (Alltech Associates, Inc., Deerfield, IL) maintained at 37 °C. The voriconazole, hydroxyitraconazole (HyITZ) and ITZ peaks were eluted at approximately 5.3, 8.5 and 18.2 min, respectively, at a flow rate of 1 mL/min, injection volume of 100  $\mu$ L, and an absorption wavelength of 225 nm. The limit

of detection and quantification for HyITZ and ITZ were 10 ng/mL and 30 ng/mL, respectively.

#### **4.3.13 Pharmacokinetic Analysis**

Pharmacokinetics of 24-hr lung and serum was assessed for the pulmonary delivery of nebulized aerosols of HP $\beta$ CD-ITZ aqueous solution and URF-ITZ colloidal dispersion to mice. A noncompartmental model was used to determine pharmacokinetic profiles for the ITZ concentrations in lung tissue using WinNonlin Professional Version 2.1 (Pharsight Corporation, Mountain View, CA). Using this method of analysis,  $T_{\max}$  and  $C_{\max}$  were determined directly from the empirical data; area under the plasma concentration-time curve (AUC) was calculated by the linear trapezoidal rule. Plots of the log concentration of ITZ and HyITZ in serum versus time revealed a first-order absorption phase and a first-order elimination phase. A one-compartmental analysis was therefore used. The  $K_{10 \text{ elimination}}$  rate constants were determined by linear regression of the points of the log-linear plasma concentration versus time curve. The  $K_{01 \text{ absorption}}$  rate constants were determined by residual method. The  $t_{1/2}$  was defined as  $0.693/\text{rate constant } K$ .

#### **4.3.14 Statistical Analysis**

Drug concentrations in lung tissue and serum were presented as mean with standard deviation (SD) ( $n = 6$ ) at each sampling time point. The data were statistically analyzed by one-way Analysis of Variance (ANOVA) followed by Tukey's post hoc analysis using OriginPro 7.5 (OriginLab Corporation, Northampton, MA), and Microsoft Excel 2003. A  $p$ -value of  $< 0.05$  was considered as statistically significant.

#### **4.4 RESULTS AND DISCUSSION**

To improve the bioavailability resulting from poor water solubility, CDs and their derivatives have been used as a means to increase aqueous solubility. CDs are characteristic of a truncated cone shape with a hydrophilic exterior surface and a nonpolar cavity interior [35]. This structure allows CDs to form non-covalent host–guest dynamic inclusion complexes with drug molecules of proper sizes and polarities, leading to enhanced apparent aqueous solubility, dissolution rate, chemical stability, and bioavailability [36, 37].

Having a external and internal diameters of 1.53 nm and 0.78 nm, respectively,  $\beta$ CD provides the right fit for ITZ molecule, as the cavity internal diameter is comparable to the dimensions of substituted phenyl groups which contribute to the lipophilicity of ITZ and other azoles [15]. HP $\beta$ CD and SBE $\beta$ CD are chemically modified  $\beta$ CD with enhanced aqueous solubility and safety profiles, and there is a vast experience of use in pharmaceutical applications [38]. Despite their safety profiles, pharmaceutical dosage forms should contain as little CD as possible. Moreover, to make an ITZ solution with acceptable amount of CD for nebulization, enhancement of the complexation capacity of the chosen CD is of practical importance. HP $\beta$ CD and SBE $\beta$ CD were therefore tested in this study to select a more efficient complexing agent for solubilizing ITZ.

##### **4.4.1 Solubility Studies and In Vitro Solution Characterization**

The phase solubility studies of ITZ in various concentrations of CDs and derivatives at different pHs have been extensively investigated and reported in literature

[39, 40]. For pulmonary delivery systems, it is crucial that the formulations are physiologically compatible with the lungs. Our preliminary experiments found that higher equilibrium solubility of ITZ can be achieved in HP $\beta$ CD as compared to SBE $\beta$ CD solutions at neutral pH conditions. This result is consistent with other reports investigating interactions between CDs and antifungal azoles [40, 41]. HP $\beta$ CD was therefore chosen as the functional excipient to formulate ITZ in our study due to its stronger solubilizing.

The viscosity of the CD-containing solution is a barrier for pulmonary administration by the Aeroneb<sup>®</sup> Professional micropump nebulizer. In order to aerosolize the ITZ-CD formulation completely within a reasonable dosing duration, it is necessary to find a suitable HP $\beta$ CD concentration for the nebulizer. As can be seen from Figure 4.1., viscosity of HP $\beta$ CD solutions increases along with its concentrations. Greater than 30 min and approximately 17 min were required to nebulize 5 mL of 20% and 15% w/v HP $\beta$ CD solutions with measured viscosities of 1.40 and 1.19 cP, respectively. The 15% w/v HP $\beta$ CD solution was selected to formulate the ITZ nebulization solution, to be comparable with the URF-ITZ formulation which takes about 10 min to nebulize 5 mL of the dispersion.

The equilibrium solubility of crystalline ITZ was significantly enhanced from 1 ng/mL in water [6] to 0.15 mg/mL in 15% w/v HP $\beta$ CD aqueous solution in this study, which was in agreement with the work of Brewster et al. [40]. Despite the significant increase of ITZ concentration in HP $\beta$ CD aqueous solution, the complexation efficiency was low, and was limited by the allowed amount of HP $\beta$ CD in this formulation. To further increase complexation efficiency of ITZ, amorphous pure ITZ, which has a higher

intrinsic solubility than its crystalline counterpart [42], was employed to make the ITZ inclusion complex with HP $\beta$ CD. As shown in Figure 4.2., a concentration of 5.4 mg/mL of ITZ was achieved immediately after dispersing amorphous ITZ in 15% HP $\beta$ CD solution, presumably due to the supersaturation rendered by the amorphous state. Compared to crystalline ITZ, amorphous pure ITZ brought about a 34-times increase in equilibrium solubility in 15% w/v HP $\beta$ CD solution. An equilibrium level of 5.3 mg/mL was attained at 2 hr and was maintained up to 24 hr as a mixed effect of HP $\beta$ CD-ITZ inclusion complex formation, supersaturation stabilized by HP $\beta$ CD via nucleation, and crystal growth inhibition [43]. At 48 hr, the ITZ concentration decreased slightly to 4.6 mg/mL, which could be attributed to precipitation of supersaturated ITZ in the system.

Osmolarity is one of the important parameters to be considered for physiological compatibility of pulmonary formulations. Sodium chloride (NaCl) was used to adjust the osmolarity of HP $\beta$ CD aqueous solutions. The filtered HP $\beta$ CD-ITZ solution that was sampled at 24 hr containing 5.3 mg/mL of ITZ, 150 mg/mL of HP $\beta$ CD and 0.54 mg/mL of NaCl was found to be isotonic with an osmolality ranging from 290 to 310 mOsm/kg and a measured pH of 6.8. The lung lining fluid was reported to be either isotonic or slightly hypotonic and slightly acidic (pH 6.9) relative to plasma [44], hence the good compatibility of the HP $\beta$ CD-ITZ solution with the lung fluid was evident. With considerably high levels of dissolved ITZ and a physiological pH value, the HP $\beta$ CD-ITZ isotonic solution was shown to be suitable for *in vivo* dosing as solubilized form of ITZ.

## 4.4.2 Solid State Analysis of Inclusion Complexes

### 4.4.2.1 DSC

DSC is used in pharmaceutical area to establish the identity and purity of solid-state systems and detect interaction of the components. Incorporation of a guest molecule in CD cavity can cause disappearance or shifting of its melting, boiling and sublimation points [45]. The thermograms of the pure components, physical mixture and lyophilized powder of HP $\beta$ CD-ITZ are presented in Figure 4.3. Micronized crystalline ITZ demonstrated a single, defined endotherm at 171.9 °C, corresponding to its melting point. The thermogram of pure HP $\beta$ CD powder exhibited a broad endothermic peak between 50-120 °C, corresponding to the dehydration of HP $\beta$ CD [46], since  $\beta$ CD did not produce any peaks of interest when examined by DSC [47]. In the physical mixture, the characteristic melting peak of ITZ appeared at 168.3 °C but with much lower intensity due to the dilution by HP $\beta$ CD, indicating the absence of significant drug–cyclodextrin interactions. For the dry powder of HP $\beta$ CD-ITZ, no appreciable endothermic event associated with the melting of ITZ was observed, suggesting the formation of true inclusion complexes between ITZ molecules and HP $\beta$ CD at a weight ratio of 5.3: 150 (molar ratio of 1:12).

### 4.4.2.2 FTIR analysis

FTIR spectra of pure ITZ, pure HP $\beta$ CD, physical mixture (ITZ: HP $\beta$ CD= 5.3: 150, weight ratio), and lyophilized dry powder of HP $\beta$ CD-ITZ are presented in Figure 4.4. The characteristic bands of pure ITZ occurred at 3126 and 3069 cm<sup>-1</sup> due to absorption of the NH<sub>2</sub> groups; at 2962 cm<sup>-1</sup> due to CH<sub>2</sub> stretching and the large peak at 1698 cm<sup>-1</sup> due to C=O stretching. The wave numbers observed at 1609 and 1425 cm<sup>-1</sup>

were assigned to the C=N and C-N bonds respectively. The bands at 1510 and 1451  $\text{cm}^{-1}$  are due to C-H deformation. These characteristic bands are consistent with previous reports [48]. The fingerprint region (1400-600  $\text{cm}^{-1}$ ) contains a large number of bands characteristic of vibration within the molecule. Changes in the FTIR spectra such as shift of characteristic bands, disappearance or reduction in intensity, and appearance of new bands might be related to possible drug-CD interaction and/or amorphization of the product [49].

The spectral pattern of the physical mixture corresponds to the sum of the band positions of the FTIR spectra of both ITZ and HP $\beta$ CD although the intensity of the ITZ bands are low due to the low weight ratio of ITZ. The results indicated no or minor interaction between ITZ and HP $\beta$ CD molecules in the physical mixture. In contrast, the spectra of the dry powder of HP $\beta$ CD-ITZ demonstrated complete smoothing of the ITZ characteristic bands that were seen in the physical mixture spectra. Additionally, smoothing was evident for bands situated between wave numbers of 1170-1010  $\text{cm}^{-1}$  as compared to those of the pure HP $\beta$ CD and physical mixture, indicating interactions occurring in the HP $\beta$ CD-ITZ dry powder.

#### **4.4.2.3 XPS analysis**

XPS is a surface sensitive technique used to probe the elemental composition of the surfaces with an analysis depth of less than 100 Å [50]. ITZ molecule ( $\text{C}_{35}\text{H}_{38}\text{Cl}_2\text{N}_8\text{O}_4$ ) is distinguished from HP $\beta$ CD molecules (empirical formula:  $\text{C}_{42}\text{H}_{70-n}\text{O}_{35}(\text{C}_3\text{H}_7)_n$ ) present in the HP $\beta$ CD/ITZ systems due to the presence of two chlorine atoms and eight nitrogen atoms in the ITZ molecule, which can be used as probing markers. As  $\beta$ CD has an external diameter of 1.53 nm and internal diameter of

0.78 nm, encapsulated ITZ in its cavity can not be detected by XPS but ITZ molecules situated on the outside surface can be probed by its elemental markers.

The atomic concentration (%) of carbon, oxygen, nitrogen and chlorine on the surface of the lyophilized dry powders of HP $\beta$ CD/ITZ inclusion complex sampled at 1, 24 and 48 hr after dispersing amorphous ITZ in 15% HP $\beta$ CD as well as the physical mixture are presented in Table 4.1. The detection of 4.99% nitrogen and 0.65% chlorine on the surface of the physical mixture demonstrated the presence of free ITZ molecules. A decrease in chlorine and nitrogen content is observed in the HP $\beta$ CD/ITZ inclusion complex sampled at 1 hr, suggesting that considerable portion of ITZ molecules hidden from the surface. In the HP $\beta$ CD/ITZ inclusion complexes sampled at 24 and 48 hr, chlorine and nitrogen were no longer quantifiable, suggesting the majority of the ITZ molecules in the systems were encapsulated inside the HP $\beta$ CD cavities and also possibly within micelles formed by HP $\beta$ CD aggregation [51]. XPS data provided evidence of interactions between ITZ and HP $\beta$ CD molecules by ruling out the existence of free, unencapsulated ITZ molecules from the powder surface.

Based on the solid state characterizations by DSC, FTIR and XPS, it can be concluded that in the HP $\beta$ CD-ITZ solution sampled at 24 hr, the majority of ITZ molecules were encapsulated, forming dynamic inclusion complexes. ITZ molecules inside the CD cavities were in equilibrium with free ITZ molecules in the solution. The focus of this study is the *in vivo* pharmacokinetic profiles following pulmonary administration of solubilized ITZ molecules as compared to ITZ nanoparticles. In consideration of the time to attain and maintain a high concentration of ITZ in solution, and based on the observations from the solubility studies and solid state characterizations,

the filtrate sampled at 24 hr from the amorphous ITZ dispersion in 15% HP $\beta$ CD isotonic solution (ITZ:HP $\beta$ CD=5.3:150 by weight ratio) was selected as the solubilized ITZ solution for *in vivo* dosing.

#### 4.4.3 Aerodynamic Particle Size Analysis

HP $\beta$ CD-ITZ solution and URF-ITZ colloidal dispersion (equivalent to 5.3 mg/mL of ITZ) as depicted in Figure 4.5. were aerosolized using an Aeroneb<sup>®</sup> Professional micropump nebulizer. The aerodynamic particle size distributions of the nebulized aerosols were measured using the 8-stage Anderson cascade impactor with an air-flow rate of 28.3 L/min. The nebulizer produced an aqueous mist of fine droplets with sizes ranging between 1 and 4  $\mu$ m, which falls within the optimal size range of 1-5  $\mu$ m for effective aerosol delivery into the deep lung after inhalation [52]. The aerodynamic parameters of the aerosols are summarized in Table 4.2. The TED of aerosolized HP $\beta$ CD-ITZ solution and URF-ITZ colloidal dispersion were 22.04 and 21.78 mg, respectively out of the total of 27 mg ITZ available for nebulization. Their corresponding fine particle doses were 11.58 and 11.93 mg. Fine particle dose was defined as TED  $\times$  FPF, the amount of aerosol droplets entering the impactor that was less than 4.7  $\mu$ m, representing the dose delivered to the deep lung. The MMAD of the aerosol droplets from nebulized HP $\beta$ CD-ITZ solution and URF-ITZ colloidal dispersion were 3.19 and 2.80  $\mu$ m, respectively with GSD of 2.28 and 2.83, respectively, indicating their suitability for deep lung delivery.

#### 4.4.4 Pharmacokinetic Study of Single Dose Inhalation in Mice

The mice were exposed to the single dose aerosols of the nebulized HP $\beta$ CD-ITZ solution and URF-ITZ colloidal dispersion (equivalent to 27 mg of ITZ total) for a duration of 18 and 11 min, respectively. The longer nebulization time of the HP $\beta$ CD-ITZ solution was due to its higher viscosity. The concentration-time profile of ITZ in lung tissue obtained from the single dose 24-hr pharmacokinetic study is illustrated in Figure 4.6. Immediately upon finishing nebulization of the compositions (0 hr post dosing), a  $C_{\max}$  of  $3.38 \pm 1.16$  and  $4.86 \pm 2.67$   $\mu\text{g/g}$  wet lung weight of ITZ was measured in lungs from the HP $\beta$ CD-ITZ solution and URF-ITZ colloidal dispersion dosing groups, respectively. The elimination of ITZ from lungs appeared to be 2-phased with an initial rapid elimination/distribution phase from 0 to 4 hr with  $K_{\text{distribution}}$  rate constants of 0.143 and  $0.238 \text{ hr}^{-1}$  and corresponding  $t_{1/2}$ s of 4.87 and 2.91 hr for HP $\beta$ CD-ITZ and URF-ITZ, respectively. This was followed by slow elimination from 6 to 24 hr with  $K_{\text{elimination}}$  rate constants of 0.022 and  $0.025 \text{ hr}^{-1}$  and the corresponding  $t_{1/2}$  of 30.9 and 28.0 hr for HP $\beta$ CD-ITZ and URF-ITZ, respectively (Table 4.3.). The fast elimination of ITZ from lung tissue coincided with absorption into the systemic circulation. At 24 hr post dosing, their corresponding ITZ levels in the lungs were  $0.98 \pm 0.40$  and  $0.65 \pm 0.29$   $\mu\text{g/g}$  wet lung weight, respectively, probably due to slow elimination. Their  $\text{AUC}_{0-24}$  values were calculated to be 32.0 and 27.2  $\mu\text{g}\cdot\text{hr/mL}$ , respectively. The  $C_{\max}$  of deposited ITZ in lung after a single dose inhalation of nebulized HP $\beta$ CD-ITZ solution and URF-ITZ colloidal dispersion were not statistically different, although the latter exhibited a higher mean value. This could partly be attributed to variation in rodent behavior within the dosing apparatus and breathing patterns since the two formulations demonstrated comparable MMADs (both within the 1- 4  $\mu\text{m}$  range).

The drug concentration-time profiles of ITZ and its main metabolite hydroxyl-itraconazole (HyITZ) in serum are illustrated in Figures 4.7. and 4.8., and the pharmacokinetic parameters of ITZ and HyITZ are listed in Table 4.4. The  $C_{\max}$  of ITZ for the HP $\beta$ CD-ITZ solution and URF-ITZ colloidal dispersion dosing groups were  $0.48 \pm 0.11$  and  $0.55 \pm 0.084$   $\mu\text{g/mL}$  measured at 1.5 and 3 hr after dosing, respectively. Their corresponding  $K_{01}$  absorption and  $K_{10}$  elimination rate constants were  $0.679$  and  $0.718$   $\text{hr}^{-1}$ , and  $0.144$  and  $0.168$   $\text{hr}^{-1}$ , respectively, indicating a much faster absorption and slower elimination of ITZ from HP $\beta$ CD-ITZ solution as compared to URF-ITZ nanoparticle dispersion. The corresponding  $\text{AUC}_{0-\infty}$  values were  $3.26$  and  $4.17$   $\mu\text{g}\cdot\text{hr/mL}$ .

Upon absorption into systemic circulation, ITZ is primarily metabolized in the liver by a large number of pathways producing more than 30 metabolites. The major metabolite, HyITZ, has considerable antifungal activity similar to that of ITZ and contributes to the overall potent antifungal properties of ITZ [53, 54]. In this study, the  $C_{\max}$  of HyITZ for HP $\beta$ CD-ITZ and URF-ITZ dosing group were  $0.49 \pm 0.14$  and  $0.64 \pm 0.17$   $\mu\text{g/mL}$  at 2 and 4 hr post dosing, respectively, exhibiting a lag-time between 30 to 60 minutes with respect to the  $t_{\max}$  of the parent compound. The  $K_{01}$  and  $K_{10}$  rate constants of HyITZ in serum are very similar to those of ITZ. Their  $\text{AUC}_{0-\infty}$  values were  $3.98$  and  $5.26$   $\mu\text{g}\cdot\text{hr/mL}$ , respectively. HyITZ reached higher plasma concentrations than the parent compound, in agreement with the literature [55]. However, HyITZ levels in lung tissues were not quantifiable because they were below the detection limit of the HPLC method. This is because drug-metabolizing enzymes exist in much lower concentrations in the lungs than the liver and gastrointestinal tract [56].

The pharmacokinetic profile of inhaled HP $\beta$ CD-ITZ in the lungs and blood differed substantially from the findings by Tolman and coworkers [33] who administered a single dose (6.25 mg/mL, 5 mL) of nebulized voriconazole solubilized in SBE $\beta$ CD solution (prepared by diluting the Vfend® I.V. aqueous solution) to mice. The rapid absorption of voriconazole into systemic circulation was observed with  $t_{\max}$  values of 20 to 30 min in plasma after completion of dosing, similar to pharmacokinetics following intravenous drug administration [33]. Moreover, elimination of voriconazole from lung tissue was relatively fast such that the drug level was undetectable after 6–8 hr while the plasma levels remained quantifiable for up to 24 hr post dosing. In contrast, inhalation of HP $\beta$ CD-ITZ aerosols resulted in ITZ  $t_{\max}$  of 1.6 hr in blood and ITZ levels in lung were still high at about 1  $\mu$ g ITZ/g wet lung weight at 24 hr post dosing. This is a notable finding since both of the triazoles were solubilized in solutions of  $\beta$ CD derivatives and the *in vivo* experiment conditions were similar.

Literature regarding the pulmonary applications of cyclodextrin in formulating poorly-water soluble drugs is limited, despite increasing interest in pulmonary delivery of therapeutics. Little has been reported about the pharmacokinetics of drugs and CDs following pulmonary administration. The most significant barrier to absorption of inhaled drug is the pulmonary epithelium [57]. Cabral Marques et al. [58] studied the absorption of several cyclodextrin derivatives themselves following intratracheal instillation into rabbits. Interestingly, the bioavailabilities of intratracheal instilled  $\beta$ CD, dimethyl- $\beta$ CD and HP $\beta$ CD were found to be as high as 66, 74 and 80%, respectively. These values were considerably higher than CD absorption following oral administration. The systemic absorption of CD molecules from the gastrointestinal tract is limited because of their bulkiness and hydrophilicity [59]. However, CDs can permeate the pulmonary Calu-3

cells, suggesting the ability of HP $\beta$ CD to be absorbed into systemic circulation from the lungs [60]. The  $t_{\max}$  in plasma for HP $\beta$ CD was reported to be about 113 min as compared to 20-30 min for  $\beta$ CD and dimethyl- $\beta$ CD, and the plasma elimination of the three CDs seemed to be independent of the route of administration [58]. In our study, the pharmacokinetic profile of nebulized HP $\beta$ CD-ITZ in serum showed an initial lag phase prior to reaching  $C_{\max}$  at about 90 min and a prolonged post-peak decline such that ITZ levels were still detectable at 24 hr. These features were well matched with the reported pharmacokinetic profile of pure HP $\beta$ CD following lung administration [58]. Therefore, it appears that the pharmacokinetics of ITZ from the inhaled HP $\beta$ CD-ITZ formulation seemed to have been modified to follow the pharmacokinetics of HP $\beta$ CD.

However, the present findings contradict previous reports which had demonstrated the absence of influence of CD on pharmacokinetics of drugs. Previous researchers attempted to use HP $\beta$ CD as a carrier to modify pulmonary absorption of small, hydrophobic molecules, with a hypothesis that inclusion of a guest molecule within HP $\beta$ CD that can also be absorbed would present a larger entity for absorption. Marques et al. [58] made an HP $\beta$ CD-salbutamol complex, with the intent of slowing the pulmonary absorption of salbutamol in rabbits. Unexpectedly, the pulmonary absorption of salbutamol was not significantly extended by HP $\beta$ CD complexation. The authors suggested that drug-HP $\beta$ CD complexes with larger stability constants may display extended absorption profiles with a decrease in the apparent rate of drug absorption. A subsequent study [61] employed HP $\beta$ CD for delaying the absorption of rolipram and testosterone (with stability constants of 260 and 12 000 M<sup>-1</sup>, respectively, versus 60-70 M<sup>-1</sup> for salbutamol) in rats. It was also observed that HP $\beta$ CD exerted little effect on rolipram absorption and no effect on testosterone absorption *in vivo*. The authors

suggested that rapid dissociation of the drugs from HP $\beta$ CD may be occurring *in vivo* due to the potential competition of endogenous cholesterol with these drugs for the CDs.

To explore the potential reasons for the discrepancy in pharmacokinetics observed between the above reported studies and our current work, the movement of the inhaled HP $\beta$ CD-ITZ aerosols from deposition into alveoli to absorption into systemic circulation was examined mechanistically.

Each droplet of the nebulized aerosol of HP $\beta$ CD-ITZ contains many ITZ molecules predominantly encapsulated inside HP $\beta$ CD as demonstrated *in vitro*. The inhaled aerosol deposited mainly in lung alveoli as characterized by their MMAD. In the alveoli, the nebulized droplets containing HP $\beta$ CD-ITZ coalesced into the thin layer of lung lining fluid. Total alveolar fluid volume for mice was estimated to be 10  $\mu$ L, based on the alveolar surface area of 680 cm<sup>2</sup> for mice [62] as compared to a total alveolar surface area of 1,022,000 cm<sup>2</sup> and average alveolar surface fluid volume of 15 mL in a human [56, 63]. Moreover, based on the lung drug deposition of 3.38  $\mu$ g ITZ/g wet lung weight upon completing nebulization and an average mouse lung weight of 0.16 g, an estimated mass of 0.54  $\mu$ g ITZ (equal to 0.1  $\mu$ L of the HP $\beta$ CD-ITZ solution used) was deposited in each mouse lung. The deposition of inhaled HP $\beta$ CD-ITZ has insignificant influence on the volume of lung lining fluid. Therefore ITZ concentration in the lung lining fluid is estimated to be 54  $\mu$ g/mL (i.e. 0.54  $\mu$ g ITZ/10  $\mu$ L total alveolar fluid volume), which is dramatically higher than the equilibrium solubility of ITZ of about 10 ng/mL in simulated lung fluid as previously reported [29]. Meanwhile, the inhaled HP $\beta$ CD-ITZ was diluted 100-times following lung deposition. HP $\beta$ CD-ITZ is present as dynamic inclusion complexes without irreversible covalent bonds. The ITZ molecules

contained within the HP $\beta$ CD cavities were in equilibrium with free ITZ molecules in the lining fluid. The major driving force for drug release from these dynamic inclusion complexes is simple dilution [64, 65]. Only at rare occasions when the binding stability constants are greater than  $10^5 \text{ M}^{-1}$ , the persistence of the drug and CD interaction was probable despite dilution. Generally, the stability constant values are found within the range of  $10 - 1 \times 10^3 \text{ M}^{-1}$  while values of  $1 \times 10^4 \text{ M}^{-1}$  were seen occasionally. With reported binding stability constants of ITZ/HP $\beta$ CD 1:1 complexes of 1000-2000  $\text{M}^{-1}$  at pH 7 [6, 66], dissociation of ITZ from the inclusion complexes may presumably occur easily owing to the significant concentration decrease of free ITZ molecules.

Once ITZ was released from the host HP $\beta$ CD, it followed its inherent pharmacokinetics and was absorbed across the mucosal membrane [67, 68]. For drugs with low solubility, the mass transport of the drugs across the GI tract mucosal absorption surface was proposed to be equal to the solubility times the permeability [69]. Applying this equation to lung epithelium, the systemic absorption rate of a drug deposited within the lungs is determined by the product of its membrane permeability (P), the available surface area over which it is spread (A), and the drug concentration in the fluids (C), *i.e.* absorption rate =  $P \times A \times C$ . The drug concentration in blood is assumed to be insignificant as compared to the lung concentration and the transfer from lung to blood is irreversible [70]. Since the inhaled aerosol droplets mainly deposited in the lung alveoli where the barrier is the thinnest [56], the value for A is fixed. Since HP $\beta$ CD-ITZ in the lung lining fluid was still effectively solubilized, solubilization was not a rate-limiting step any more. Thus, permeability of ITZ through lung epithelium seemed to be the factor controlling the rate of molecular transport. It is widely accepted that small, mildly hydrophobic molecules can show extremely rapid absorption kinetics from the lungs [57].

Typical drug molecules with a log P value (octanol–water partition coefficient) greater than 1 are expected to be absorbed, with absorption half-lives (*i.e.*, the time required for half of the total number of molecules deposited in the lungs to disappear from the tissue) of approximately 1 minute or so [71]. According to this principle, with a molecular weight of 349.3 and moderate lipophilicity (log P =1.8) [72], voriconazole was well matched with the criteria for high permeability across mucosal membranes. This may explain the rapid and high extent distribution of voriconazole from lung to systemic circulation after its delivery to the deep lung. In contrast, ITZ molecule is larger (MW: 705.6) and has a calculated log P value of 6.2 [6] suggesting its poor permeability. Classified as a BCS class II drug, ITZ was deemed to have high membrane permeability. However, this is relative to its extremely low solubility. In the absence of poor solubility, permeability seems to have emerged as the primary factor that hindered drug absorption across the mucosal membrane.

Tolman et al. [33] used an approximation of the drug partition coefficient (based on the lung-to-plasma ratios of  $C_{\max}$  and  $AUC_{0-6}$ ) with the calculated values between 1.4 - 1.6 to explain the fast absorption and distribution of voriconazole across lung mucosal surfaces to systemic circulation with minimal drug retained in lung tissue. Accordingly, after inhalation of the nebulized aerosols of HP $\beta$ CD-ITZ, the calculated partition coefficients for  $C_{\max}$  and AUC were 9.7 and 12.7, respectively, suggesting a relatively poor transport of ITZ from lung to systemic circulation. The calculated partition coefficients for the inhaled URF-ITZ colloidal dispersion were 9.9 and 7.3, respectively, falling into the same range. Therefore, it was apparent that the calculated partition coefficient of ITZ was independent of the formulations used in this study.

Based on the dynamic equilibrium between free ITZ and the inclusion complexes, there should still be a considerable portion of ITZ remaining as HP $\beta$ CD-ITZ complexes in the lung lining fluid. It could be possible that ITZ was carried across the lung epithelium together with HP $\beta$ CD by paracellular diffusion due to the hydrophilicity of HP $\beta$ CD [57]. However, the apparent permeability coefficient of HP $\beta$ CD is rather low, based on the typical measured permeabilities of molecules with similar sizes and hydrophilicities in lung cell culture, which range from  $10^{-7}$  to  $10^{-8}$  cm/s [73]. Thus, HP $\beta$ CD-ITZ inclusion complexes may move across the lung epithelium fairly slowly. It is reported that the time required for HP $\beta$ CD to reach the maximum plasma level was 113 min (1.9 hr) in rabbit after intratracheal instillation [58], which approximate the ITZ  $T_{\max}$  of 1.5 hr in serum in the present study. Absorption of ITZ as HP $\beta$ CD-ITZ inclusion complexes from lung epithelium could be one of the potential mechanisms contributing to the total transport of ITZ from lung to blood after inhalation of nebulized HP $\beta$ CD-ITZ solution.

In comparison, upon deposition of the inhaled aerosol droplets containing URF-ITZ (ITZ:mannitol:lecithin=1:0.5:0.2, weight ratio) nanoparticles in the lung lining fluid, they underwent rapid dissolution and were able to attain and maintain high magnitude of supersaturation, as indicated in simulated lung fluid *in vitro* [29]. The rate and extent of dissolution, as well as permeability across mucosal membrane influenced the absorption rate of ITZ through the lung epithelium to reach systemic circulation. Worthy to note is the role of lecithin which contains mainly dipalmitoylphosphatidylcholine (DPPC), the primary component of endogenous human lung surfactant [74]. Besides playing an important role in improving the wettability of the nanoparticles containing ITZ, lecithin also acted as a permeation enhancer. It could induce changes in the cytoskeleton which

affect tight junctions and accelerate paracellular passages of drugs [75], resulting in enhanced permeation of ITZ molecules through lung epithelium into systemic circulation. In the present study, the higher  $C_{\max}$  and AUC of ITZ in serum of mice inhaled nebulized URF-ITZ colloidal dispersion, compared to mice inhaled HP $\beta$ CD-ITZ solution, may be attributed to the permeation enhancement of lecithin in the URF-ITZ composition.

Since ITZ in HP $\beta$ CD-ITZ solution is effectively solubilized, it was immediately available for absorption. The elimination of the phase-to-phase transition which limited bioavailability [37], rendered HP $\beta$ CD-ITZ about 1.3 hr faster in reaching  $t_{\max}$  as compared to URF-ITZ colloidal dispersion that required a prior dissolution step of the nanoparticle matrices.

In our previous report, where mice inhaled a nebulized URF-ITZ colloidal dispersion at a single dose of 100 mg ITZ equivalent (5 mL  $\times$  20 mg ITZ/mL dispersion), an ITZ  $C_{\max}$  of 21.19  $\mu$ g/g wet lung weight and 1.64  $\mu$ g/mL in serum was achieved [29]. In this study, under the identical *in vivo* experimental conditions, except for the reduction of ITZ dosage to about one-fourth of the previously used dose, very similar drug concentration-time curves in lung and serum were observed with  $C_{\max}$  values of 4.86  $\mu$ g/g wet lung weight and 492 ng/mL, respectively. Those values were almost proportional to the dose reduction, suggesting non-saturable absorption of inhaled URF-ITZ colloidal dispersion from lung to systemic circulation over a wide concentration range. This implies the capacity to choose a flexible dosing regimen.

## 4.5 CONCLUSION

An aqueous solution containing 5.3 mg/mL of ITZ in inclusion complex with HP $\beta$ CD suitable for deep lung delivery using the Aeroneb<sup>®</sup> micropump nebulizer was made of amorphous ITZ without other excipients. Inhalation of nebulized aerosols of the aqueous ITZ solution and a nanoparticulate ITZ colloidal dispersion produced similar ITZ lung depositions due to comparable aerodynamic properties of the aerosols. Solubilized ITZ exhibited faster systemic absorption than the nanoparticulate ITZ colloidal dispersion due to the elimination of phase-to-phase transition that required for ITZ release from nanoparticulates. Permeability of ITZ across the lung epithelium becomes the rate-limiting factor that hindered the solubilized ITZ from achieving rapid systemic absorption, as compared to other reported inhaled drug solutions.

## **Appendix A: Prophylaxis Study of Inhaled Itraconazole against Invasive Pulmonary Aspergillosis**

### **A.1 INTRODUCTION**

The ultimate aim of developing new itraconazole (ITZ) formulation and alternative administration route compared to the conventional formulations is to improve bioavailability of drug and thereby therapeutic effect. For treating invasive aspergillosis, survival in fungal infected animal model is probably the most meaningful difference can be shown between the control and the fungal infected group.

As characterized in previous chapters, aqueous colloidal dispersion of URF-ITZ nanostructured aggregates (URF nanotechnology processed ITZ:mannitol:lecithin =1:0.5:0.2 by weight ratio) has demonstrated excellent in vitro properties for deep lung deliver by nebulization. Furthermore, single-dose inhalation of the nebulized aerosols of the URF-ITZ aqueous colloidal dispersion produced considerable lung deposition (more than 20 µg/g wet lung tissue) and systemic ITZ level (1.64 µg/mL) in mice [1]. Based on the promising pharmacokinetic profiles of the inhaled URF-ITZ and prophylaxis studies of previously developed pulmonary ITZ formulations [2, 3], we are therefore interested to see the preventing effect of inhaled URF-ITZ against invasive fungal infections on *Aspergillus fumigatus* inoculated immunosuppressed mouse model.

### **A.2 ANIMAL MODEL**

An established murine model of invasive pulmonary aspergillosis was used as previously described [2, 4]. Female ICR mice (Harlan Sprague Dawley, Inc.,

Indianapolis, IN) were immunosuppressed by intraperitoneal cyclophosphamide (250 mg/kg) and subcutaneous cortisone acetate (250 mg/kg) two days prior to inoculation. Both cyclophosphamide (200 mg/kg intraperitoneal) and cortisone acetate (250 mg/kg subcutaneously) were re-administered on day 3 post-inoculation, and mice received antibiotic prophylaxis with ceftazidime 50 mg/kg/day. This study was approved by the Institutional Animal Care Use Committee at the University of Texas Health Science Center at San Antonio, and all animals were handled in accordance with the American Association for Accreditation of Laboratory Animal Care.

For inoculation, mice were placed inside an acrylic chamber, and *A. fumigatus* conidia were introduced by aerosolizing the conidial suspension with a small particle nebulizer (Hudson Micro Mist, Hudson RCI, Temecula, CA) driven by compressed air [4]. A standard exposure time of 1 hour was used to allow for complete aerosolization of the conidial suspension. Starting inocula were assessed by colony forming unit (CFU) enumeration from mice one hour post-inoculation.

### **A.3 ANTIFUNGAL THERAPY**

Mice were assigned to three treatment groups: inhaled nebulized aerosol of URF-ITZ (ITZ:mannitol:lecithin=1:0.5:0.2 by weight ratio) colloidal dispersion (20 mg/mL × 10 mL, twice daily), amphotericin B deoxycholate (1 mg/kg intraperitoneally daily; Apothecon, Princeton, NJ), or aerosolized purified water as control in a whole-body exposure dosing chamber [5] using a Aeroneb® Pro micropump nebulizer with air-flow of 1 L/min to blow the aerosol into the chamber. Prophylaxis was begun two days prior to pulmonary inoculation and continued for a total of 10 days (day 7 post-inoculation).

Animals that appeared moribund prior to the end of the study were euthanized by halothane and death was recorded as occurring the next day.

The prophylaxis study of inhaled URF-ITZ colloidal dispersion in fungal infected mice model was performed by Dr. Nathan Wiederhold in the University of Texas Health Science Center at San Antonio.

#### **A.4 SURVIVAL RESULTS**

The prophylaxis study results are presented in Figure A.1. URF-ITZ dosing group showed similar survival rate compared to mice dosed amphotericin B in both short term (8 days) and long term (12 days). However, both of the antifungal treatment groups demonstrated lower percent survival than the control group which inhaled nebulized water. The 8 days survival on therapy in control group was 75%, which may indicate the fungal infection mouse model was not successful. The URF-ITZ and amphotericin B administration groups were 55 and 50%, respectively. This may imply possible toxic side effects associated with the antifungal agents used in this study. Further investigation of the drug interactions on this specific mouse model is needed.

Figure A.1. Survival curves for immunosuppressed mice that inhaled nebulized aerosol of URF-ITZ (ITZ:mannitol:lecithin=1:0.5:0.2 by weight ratio) colloidal dispersion (20 mg/mL  $\times$  10 mL, twice daily), amphotericin B deoxycholate, or control (aerosolized purified water) and challenged by pulmonary inoculation with *A. fumigatus*.

## **Appendix B: Study of Interaction of Cyclophosphamide and Inhaled Itraconazole**

### **B.1 INTRODUCTION**

Aqueous colloidal dispersion of URF-ITZ (URF nanotechnology processed ITZ:mannitol:lecithin=1:0.5:0.2) has demonstrated excellent in vitro properties for deep lung deliver by nebulization. Furthermore, single-dose inhalation of the nebulized aerosols of the URF-ITZ aqueous colloidal dispersion produced considerable lung deposition and systemic itraconazole (ITZ) level (1.64  $\mu\text{g/mL}$ ) in mice [1]. Because of the promising pharmacokinetic profiles of the inhaled URF-ITZ, prophylaxis studies of inhaled URF-ITZ on fungi inoculated immunosuppressed mice were conducted in the University of Texas Health Science Center at San Antonio. However, the prophylaxis study showed no significant improvement of the survival rate in mice administered ITZ compared to the control.

To establish the immunosuppressed mouse model, a combination of cortisone acetate and cyclophosphamide (CY) were employed. CY is a phosphoramidate form of nitrogen mustard commonly used in cancer treatment. In addition, its toxicity to lymphocytes has made it an important immunosuppressant agent in hematopoietic stem cell transplant therapies [2], and more recently in treatment of inflammatory conditions such as systemic lupus erythematosus and rheumatoid arthritis, etc. [3]. The parent drug itself is not cytotoxic. It must be activated by hepatic cytochrome P450 (CYP) enzymes and undergoes three metabolic pathways: (1) urinary elimination as unchanged CY, which account for about 25-30% of the drug metabolism; (2) detoxification via CYP

3A4/5 to dechloroethyl-cyclophosphamide (DCCY), which account for about 5-10%; and (3) the major metabolic pathway---activation via CYP 2A6, 2B6, 3A4, 3A5, 2C9, 2C18, and 2C19 to 4-hydroxycyclophosphamide (HCY) [4]. HCY is then converted by beta-elimination to toxins acrolein, which is primarily responsible for urothelial toxicity, and phosphoramidate mustard (PM), responsible for antineoplastic activity. Other metabolites include o-carboxyethyl-phosphoramidate mustard (CEPM), 4-keto-cyclophosphamide (ketoCY), and hydroxypropyl-phosphoramidate mustard (HPPM) [3, 5]. The schematic of CY metabolic pathways is shown in Figure B.1.

Antifungal azole drugs function by inhibiting the fungal CYP enzyme 14- $\alpha$ -sterol-demethylase which is involved in cell membrane biosynthesis [6]. ITZ is a known potent inhibitor of CYP 3A4 and has many clinically significant drug interactions associated with this enzyme inhibition [7]; whereas fluconazole is a relatively potent inhibitor of CYP 2C9 [8].

Published toxicity data from a randomized trial comparing fluconazole with ITZ as antifungal prophylaxis in hematopoietic cell transplant recipients demonstrated a disequilibrium in CY metabolites, and renal and hepatic toxicities in patients who received the azole drugs concurrent with CY-containing regimens [9, 10]. Coadministration of high-dose fluconazole (400 mg daily) with CY was associated with greater exposure to CY and DCCY, whereas ITZ (2.5 mg/kg 3 times daily) was associated with greater exposure to HCY, ketoCY, and CEPM [9]. In addition, concurrent fluconazole was associated with less renal and hepatic toxicity, and a trend to improved survival at day 20 [11]. Recipients of ITZ demonstrated higher exposure to toxic metabolites than recipients of fluconazole, suggesting differential inhibition of hepatic CYP450 isoenzymes can affect CY metabolism and conditioning-related toxicities [12].

We therefore suspect that drug interaction between CY and ITZ occurred in the prophylaxis studies, and the resultant toxic metabolites lead to the unexpected lower survival rate of the fungal infected immunosuppressed mice with ITZ therapy. This study is designed to confirm this hypothesis.

To quantify the metabolites of CY, LC-MS need to be used. However, HCY and AldoCY are very unstable ( $t_{1/2} = \sim 4$  min). Moreover, PM and acrolein are toxic and unstable; they might bind to protein or react with tissue, hard to extract out, and easily decompose [13, 14]. CEPMP is the only chemically stable major CY metabolite formed between the activation of CY to HCY and the ultimate formation of glutathione conjugates of acrolein and PM. ITZ can inhibit P4503A4, then the inactivation pathway product DCCY may be decrease [15]. Based on these, CEPMP and DCCY were selected as markers to monitor the change of CY toxic metabolites with concomitant ITZ therapy.

## **B.2 MATERIALS AND METHODS**

### **B.2.1 Materials**

CY is produced by Baxter Health Corporation (Deerfield, IL). CEPMP and DCCY were purchased from Eno Research Chemicals and Custom Synthesis Eno Research & Consulting Services, LLC (Hillsborough, NC). Cortisone acetate was purchased from Sigma. Ceftazidime is manufactured by Sandoz GmbH for Hospira Worldwide Inc., (Lake Forest, IL). ITZ was purchased from Hawkins Chemical (Minneapolis, MN).

### **B.2.2 *In vivo* study design**

The immunosuppressed mouse model will be established as follows. Mice (weighing between 18 - 22 g, female) with access to sterile food and water ad libitum, will be rendered immunosuppressed by intraperitoneal CY (250 mg/kg) and subcutaneous cortisone acetate (250 mg/kg) on Day-1. Both CY (200 mg/kg intraperitoneally) and cortisone acetate (250 mg/kg subcutaneously) were re-administered on Day-6. The mice will inhale ITZ aerosols from Day-1 for 10 days, 100 mg ITZ equivalent in 5 mL  $\times$  2 each time, twice per day. The immunosuppressed mice need housing in the barrier facility to ensure the health and safety. In addition, mice will receive a daily dose of the antibiotic ceftazidime (50 mg/kg) subcutaneously (0.2 mL/mouse) to prevent bacteria infection from Day-1. The mice will be divided into 5 groups as following.

Group 1: Aerosolized ITZ + Cyclophosphamide & cortisone acetate (same immunosuppression regimen used in the prophylaxis study)

Group 2: Aerosolized ITZ + cortisone acetate (no Cyclophosphamide)

Group 3: Cyclophosphamide + cortisone acetate (no aerosolized ITZ)

Group 4: Cortisone acetate alone

Group 5: Normal mice without any treatment

The treatment of the mice listed schematically in Figure B.2.

### **B.2.3 Sampling of blood**

Blood samples will be taken by cardiac puncture and place into tubes containing EDTA (ethylenediaminetetraacetic acid), mixed and centrifuged immediately after withdrawn. Plasma will be immediately removed, frozen and stored at -80 °C until analysis.

#### **B.2.4 Analysis of CY metabolites by using mass spectrometry-HPLC (LC-MS)**

The Applied Biosystems 4000 Q Trap LC-MS/MS system with ESI, APCI and nanospray sources coupled with Shimadzu LC-20AD HPLC system (Shimadzu, Columbia, MD) located in the Analytical Instrumentation Facility Core (PHR 1.110) at The University of Texas at Austin was employed for quantitation of CY stable metabolites DCCY and CEPM, as well as ITZ. The LC-MS/MS method development was performed by Dr. Herng-Hsiang Lo in the CRED Analytical Instrumentation Facility Core supported by NIEHS center grant ES07784.

#### **B.2.5 Bioassays of mice plasma and organ histology**

Plasma creatinine, BUN, bilirubin (total and indirect), alanine aminotransferase (ALT), aspartate aminotransferase (AST), Alkaline phosphatase (ALP) will be analyzed by IDEXX for toxicity analysis.

Livers and kidneys will be collected and fixed in formaldehyde; Tissue slices may be prepared by IDEXX when necessary for histology study.

### **B.3 RESULTS**

LC-MS methods for determining the amount of ITZ, DCCY and CEPM have been established by Dr. Stony Lo. The standard curves are presented in Figures B.3, B.4, and B.5. For ITZ, there is a good linearity in the range of 50-1000 picogram (pg) can be detected by the LC-MS system used. DCCY and CEPM demonstrated good linearity in the range of 100-2000 pg and 50-1000 pg, respectively.

Figure B.1. Partial metabolic pathways of cyclophosphamide (CY). Chloroacetaldehyde (CAA), acrolein, and phosphoramidate mustard (PM) are cytotoxins, but acrolein and PM are the major toxins because of the abundance of their formation. HCY (4-hydroxy-cyclophosphamide) is formed primarily in the liver but circulates in blood, entering cells as its tautomer aldocyclophosphamide (AldoCY). Acrolein and PM are formed from AldoCY when it decomposes through beta-elimination. Other metabolites include *o*-carboxyethylphosphoramidate mustard (CEPM), deschloroethyl-cyclophosphamide (DCCY), 4-ketocyclophosphamide (KetoCY), hydroxypropyl-phosphoramidate mustard (HPPM).

## **Appendix C: Detection Recrystallization of Amorphous Formulation by Transmission Electron Microscopy**

### **C.1 INTRODUCTION**

Amorphous formulations have been developed in our laboratory to increase the aqueous solubility of poorly water-soluble drugs (i.e. itraconazole (ITZ)), thereby enhance the bioavailability which is limited by the low aqueous solubility [1, 2]. Due to the metastable character of amorphous form, it may automatically transfer to lower energy level of crystalline form during storage. Because of the instability of amorphous state, the supposed improvement of dissolution rate and extent will be affected. Conventionally, powder X-ray diffraction (XRD), differential scanning calorimetry (DSC) and dissolution test can be used to detect recrystallization of amorphous pharmaceutical products. However, they all have limitations in detecting low percentage of morphological change. It is generally accepted that only when the content of crystal is higher than 5%, it can be differentiated by XRD [3]. For the nanomaterials, the sensitivity is even lower, due to the weaker diffraction by the smaller particles of crystal. DSC is relatively more sensitive, it can quantify the amount of recrystallized material based on the energy change in a thermal event. However, it is too complicated to predict for systems with more than two components.

Solid state NMR can determine molecular structure and Intermolecular packing, therefore has been reported to use to monitor recrystallization. However, it has not been reported to detect the recrystallization of pharmaceutical amorphous nanomaterials. The

application in detecting small amount of crystal in amorphous nanomaterials will be another research focus.

With advancements in spatial and temporal resolution, instruments such as transmission electron microscopes (TEM), scanning transmission electron microscopes (STEM) have been developed with the ability to observe the evolution of material microstructure and properties [4]. We therefore explored the application of TEM in detecting small amount of recrystallization of an amorphous nano-structured aggregate of ITZ made by URF technology (i.e. URF-ITZ).

## **C.2 METHODS**

The preparation of URF-ITZ was described in previous chapters using the URF technology.

### **C.2.1 XRD**

The crystallinity of freshly made URF-ITZ powder and URF-ITZ powder stored for 12-month was examined using wide angle XRD as described in previous chapters.

### **C.2.2 TEM**

The freshly made URF-ITZ powder and URF-ITZ powder stored for 6-month were examined using TEM. The dry sample powder was placed on a Holey Carbon Support Film with 200 Mesh Copper Grids (Jed Pella, Inc., Redding, CA) and viewing on a JEOL 2010F transmission electron microscope (JEOL USA, Inc., Peabody, MA).

The TEM images were taken by Dr. Paulo Ferreira in the Materials Science and Engineering Program at The University of Texas at Austin.

### **C.3 RESULTS**

#### **C.3.1 XRD profiles**

From the XRD patterns shown in Figure C.1., the freshly prepared URF-ITZ powder exhibited broad, diffuse haloes in absence of the characteristic crystalline peaks of ITZ and mannitol, indicating its amorphous nature [5]. The URF-ITZ powder that stored for 6 months also demonstrated no appreciable characteristic crystalline peaks, suggesting its amorphousness.

#### **C.3.2 TEM in detecting recrystallization**

The TEM image in Figure C.2. illustrated a disordered mass of the freshly prepared URF-ITZ powder, indicating its complete amorphous state. In contrast, for the URF-ITZ powder that stored for 6 months as shown in Figure C.3., some areas at the edge of the powder displayed ordered morphology. Within the blue circle, regular crystal plates can be seen, compared to the disordered area within the red frame, indicating recrystallization at a few nm level. TEM can “see” the morphological difference at few nm. Compared to XRD and other techniques, TEM is highly sensitive to detect trace amount of recrystallization of amorphous product.

Figure C.1. XRD patterns of Bulk ITZ, URF-ITZ powder freshly prepared, URF-ITZ stored for 6 months, and mannitol.

Figure C.2. TEM image of URF-ITZ powder freshly prepared.

Figure C.3. TEM image of URF-ITZ powder stored for 6 months.

## **Appendix D: scanning Electron Microscopy images of lyophilized dry powders of itraconazole formulations**

### **D.1 INTRODUCTION**

To make biocompatible and biodegradable ITZ nanoparticle formulations for pulmonary delivery, various sugars, sugar alcohols, bovine serum albumin (BSA), lecithin and polysorbate 20 (Tween 20) were tested with different weight ratios. ITZ and excipients were first dissolved in a mixed solvent; the formed solution was then applied to URF process, lyophilized to obtain dry powders. The samples were mounted onto an aluminum stage using conductive carbon tape. Samples were coated using a model K575 sputter coater (Emitech Products, Inc., Houston, TX) with gold/palladium for 20 sec in a high vacuum evaporator. Scanning Electron Microscopy (SEM) was performed using a Hitachi S-4500 field emission scanning electron microscope (Hitachi High-Technologies Corp., Tokyo, Japan) operating at an accelerating voltage of 10-15 kV. SEM images are presented as follows.

### **D.2 RESULTS**

Figure D.1. SEM images of URF processed dry powder of ITZ/Lecithin=1/0.2 (w/w).

Figure D.2. SEM images of URF processed dry powder of ITZ/Lecithin=1/0.3 (w/w).

Figure D.3. SEM images of URF processed dry powder of ITZ/Lecithin=1/0.4 (w/w).

Figure D.4. SEM images of URF processed dry powder of ITZ/BSA/Lecithin=1/0.063/0.2 (w/w/w).

Note: BSA has low solubility in the mixed solvent of Dioxane/water=0.65/0.35 (v/v).

Figure D.5. SEM images of URF processed dry powder of ITZ/Dextrose/Lecithin=1/0.5/0.1 (w/w/w).

Figure D.6. SEM images of URF processed dry powder of ITZ/Lactose/Lecithin=1/0.5/0.1 (w/w/w).

Figure D.7. SEM images of URF processed dry powder of ITZ/Lactose/Lecithin=1/0.5/0.2 (w/w/w).

Figure D.8. SEM images of URF processed dry powder of ITZ/Meltose/Lecithin=1/0.5/0.1 (w/w/w).

Figure D.9. SEM images of URF processed dry powder of ITZ/Sucrose/Lecithin=1/0.5/0.1 (w/w/w).

Figure D.10. SEM images of URF processed dry powder of ITZ/Trehalose/Lecithin=1/0.5/0.1 (w/w/w).

Figure D.11. SEM images of URF processed dry powder of ITZ/Mannitol/Lecithin=1/0.5/0.2 (w/w/w).

Figure D.12. SEM images of URF processed dry powder of ITZ/Erythritol/Lecithin=1/0.3/0.1 (w/w/w).

Figure D.13. SEM images of URF processed dry powder of ITZ/Xylitol/Lecithin=1/0.3/0.1 (w/w/w).

Figure D.14. SEM images of URF processed dry powder of ITZ/Erythritol/Tween20=1/5/0.0038 (w/w/w).

Note: the critical micelle concentration (CMC) of Tween 20 is  $7.6 \times 10^{-5}$  g/mL. When the powder dispersed into water to form a dispersion of 20 mg ITZ/mL equivalent, concentration of Tween 20 is at CMC.

Figure D.15. SEM images of URF processed dry powder of ITZ/Glucose/Tween20=1/5/0.0038 (w/w/w).

Note: the critical micelle concentration (CMC) of Tween 20 is  $7.6 \times 10^{-5}$  g/mL. When the powder dispersed into water to form a dispersion of 20 mg ITZ/mL equivalent, concentration of Tween 20 is at CMC.

Figure D.16. SEM images of URF processed dry powder of ITZ/Lactose/Tween20=1/5/0.0038 (w/w/w).

Note: the critical micelle concentration (CMC) of Tween 20 is  $7.6 \times 10^{-5}$  g/mL. When the powder dispersed into water to form a dispersion of 20 mg ITZ/mL equivalent, concentration of Tween 20 is at CMC.

## **Vita**

Wei Yang was born in Yinchuan, Ningxia province, P.R. China on December 12, 1975 to Mr. Jingsen Yang and Mrs. Fengqing Wang. After she graduated from Yinchuan No. 9 High School in China in 1994, she began her undergraduate education at China Pharmaceutical University, Nanjing, China. She received the degree of Bachelor of Science (Pharmacology) in July 1999 with the honor of Top Graduate. She then pursued her graduate study in China Pharmaceutical University, and transferred to the Graduate Program in the School of Pharmacy at Memorial University of Newfoundland, St. John's, Newfoundland, Canada. She obtained her Master of Science in Pharmacy in December 2003, and worked as a Research Associate in North Atlantic Biopharma Inc. at St. John's, Canada thereafter. In September 2005, she was admitted into the Graduate School in the College of Pharmacy at The University of Texas at Austin to pursue her Ph.D. under the supervision of Dr. Williams. During Wei's graduate career she has presented her research at scientific conferences in U.S. and Canada. In 2008 and 2009 Wei was awarded the University of Texas Continuing Fellowship and Jaime N. Delgado Endowed Graduate Fellowship in Pharmacy. Parts of the chapters presented in this dissertation will be submitted for publication in several high impact pharmaceutical journals.
